reproductive strategies that couple promiscuity (thus leading possibly infanticidal males to believe that the female's offspring is theirs) with subtle morphological or behavioral cues that conceal ovulation (thus preventing male knowledge of fecundity; Knott et al. 2010).

Interactions between individuals with little relative genetic relatedness is a further risk factor for violent behavior, as indicated by higher rates of physical abuse and homicide in households in which unrelated persons live together (Daly and Wilson 1998). Nepotistic care and protection, as motivated by kin selection, can be seen as a force that reduces the likelihood of aggressive interactions among relatives compared to aggressive interactions among individuals with lower relatedness. However, within-family aggressive conflicts do occur, especially over issues of partitioning of familial resources, if conflicts of interests and direct benefits outweigh indirect benefits of favoring kin due to genetic relatedness.

It has been proposed that regulatory (i.e., leveling) social mechanisms such as public opinion, gossiping, criticism, ostracism, expulsion, and desertion diminish the risk of lethal aggression (Boehm 1999), as they may be other effective ways of eliminating or reducing the success of the competition. Examinations using cross-cultural and cross-species data have found support for this hypothesis.

Reasons for Conflict and Killing Between Groups

Competition for resources is a key feature of the evolutionary process. Scramble competition involves racing to consume resources before another individual or group can access them; contest competition involves interfering with the activities of a rival individual or group to monopolize resources, and may entail direct aggression. Contenders maximizing fitness clash with conspecifics for access to mates, cooperative partners, foraging, and resting spaces. Victorious individuals, however, may not only obtain benefits from such an endeavor, but they may also accrue several costs (e.g., risk of injury, time invested in the conflict that could be allocated to other activities, retaliation to kin or allies). This dynamic is not restricted

to animals living within one group, as intense aggression leading to clear power differentials and dominance relationships is also expected between groups (Wilson et al. 2014). Depending on the severity of the conflict, the damage inflicted on contenders can have a lethal outcome.

Early theories considered intergroup killings to be exclusive of human societies living in complex political systems such as nation-states. However, subsequent observations with subsistence societies and nonhuman primates concluded that lethal attacks across communities were not uncommon, and were in fact pervasive (Guilaine and Zammit 2008). The implications of these reports for understanding the origins of violence and intergroup aggressive conflict in human societies were met with both skepticism and opposition, as some hypothesized that the impact of modern societies on the ecologies in which studies were conducted could account for the presence of intergroup violent conflict.

As in the case of intragroup killings, cumulative nonhuman primate and mammalian data in general indicate that intergroup killings are not an outcome of human disruption of natural social ecologies (► [“Humans: Between-Group Conflicts”](#) in the chapter by Fernandes et al., this volume; ► [“Nonhuman Primates: Between-Group Conflicts”](#) in the chapter by Peñaherrera-Aguirre et al., this volume). Patterns of patrolling and lethal attacks have been found to be strategic and fitness benefits appear to be obtained through attraction of new females, induction of shorter interbirth intervals, and access to foraging patches. Rates of intergroup lethal aggression vary across mammalian taxa and are not equally affected by human presence and interference.

For decades group selection theories were largely disregarded as possible explanations for any kind of behavior, including intergroup conflict and warfare. However, more recent interest in multilevel selection models have somewhat revived the formulation of hypotheses that rely on the idea that groups can function as the unit of selection, based on the notion that phenotypes that benefit the community may be favored in spite of negative impact upon individual fitness (Choi and Bowles 2007; Woodley and Figueredo 2013). Thus several

researchers posit that ingroup altruism and intergroup warfare may have coevolved through biological and cultural group selection, with the latter being a more plausible explanation for conflicts that includes larger numbers of individuals than smaller-scale confrontations (Richerson et al. 2016). Biological and cultural group selection are not independent and separate phenomena, but are rather proposed to interact through gene-culture coevolution. The application of any form of group selection theory is however met with resistance from several fronts in evolutionary biology, anthropology, and psychology.

Warriorship (i.e., individual engagement in between-group conflicts) has also been proposed to be positively associated with individual fitness in prestate human societies (Chagnon 1988; Glowacki and Wrangham 2013). Warriors have been argued to be motivated by the opportunities for looting and capturing as a consequence of victory. Hence, by raiding, feuding or battling rival groups, warriors are thought to gain material and social benefits which can boost individual fitness. With respect to the former, some of the coveted commodities include food, weapons, tools, raw materials, livestock, ornaments, physical trophies, and territorial expansion. Similarly, captives can be taken as slaves or for execution (such as human sacrifices). Social stratification is considered as one of the cultural factors that motivate sparing the lives of the vanquished rivals. By socially integrating individuals from the defeated group, conquerors obtain economic benefits from the labor of captives, although this appears uncommon. Moreover, executions of prisoners have been considered to bolster social cohesion and legitimize the authority of leaders. It has also been hypothesized that warriors will engage in lethal violence as means for obtaining social benefits such as increasing their status in the group, accumulate wealth (not obtained during incursions), improve their marrying opportunities, obtain public recognition, and expand their network of allies. As such, different components of multilevel selection (such as individual and group selection) may interact to explain between-group aggressive conflict and killing.

Conclusion

A didactic taxonomy of aggression, lethal and nonlethal, permits examining whether certain types of violence are special adaptations, or simply byproducts of other adaptations, and at what level they are selected (e.g., with respect to individual or group-level fitness). By comparing studies of modern, industrial populations with data from prestate societies, modern or otherwise, and with nonhuman primate data, it is possible to conclude with considerable confidence that aggressive interactions among individuals and among groups are neither a feature only of civilizations, nor are they exclusive to humans, nor are they induced by a mismatch of modern or captive environments and the social ecologies to which species or populations were adapted. Killing itself may not always be functional outcome of adaptations for aggression, but neither should it be dismissed as a universally maladaptive phenomenon. The evidence strongly favors the hypothesis that intraspecific killings often have adaptive consequences for individuals and groups.

Consciousness; Self-consciousness

Definition

An ability to think about one's own mental states.

Introduction

It seems clear to me that my subjective mental states are my own. Furthermore, this act of introspection shows that I have some ability to think about my mental states. I would say that I am self-aware. Furthermore, my experience indicates that most humans have such mental states of their own, including self-awareness. The question thus arises where do these subjective mental states, including self-awareness, come from? What causes or explains their presence and content? Has this human capability evolved?

From the earliest times, discussions of consciousness have been closely related to those of free will. Volition is still for many people a definitive attribute of consciousness, which in turn is a definitive attribute of humans. Both volition and consciousness, in turn, are closely allied with rational thought. Often these three capabilities are combined as the distinctive characteristics of the human soul. For many people, the attributes of these capabilities seem entirely apparent by introspection. For all of these reasons, discussions of self-awareness and volition have often become doctrinaire, for instance, in both Judeo-Christian-Islamic-Vedic morality and Brahmanic-Buddhist-Taoist-Gnostic transcendence. Human and nonhuman animals have seemed to occupy their respective rungs on a *scala*

naturae, each of which had its distinctive attributes augmenting the rung below and subsumed by the rung above. Consciousness and its concomitant volition and rationality were the attributes that separated humans from all lower forms of life.

Modern western philosophical and theological discussions began in the sixteenth and seventeenth centuries with fundamental controversies between Christian sects about divine grace and predestination and with Descartes' subsequent dictum "Je pense donc je suis." In recent centuries, contrasting positions have developed between environmentalist and nativist theories of human perception (or between sensory and mental determinants of thought). These trends have culminated in an emphasis either on culture or on intrinsic structure as the predominant determinants of consciousness and language. In all of this history, because it was assumed that the uniqueness of humans depended on consciousness and self-awareness, there was little attention to the possibility of their evolution.

Continuity Between Human and Nonhuman Animals

Darwin's revolutionary book, *The Expression of the Emotions in Man and Animals* (1872), for the first time, proposed some continuity between the minds of humans and other animals as indicated by their respective behaviors. Since then, studies of learning and instinct, as well as the ontogeny and phylogeny, of behavior have had progressively increasing influence on thinking about consciousness and awareness. Particularly relevant have been experiments that explore the limits of nonhuman intelligence. These experiments have raised difficult questions about the relationships among language and thought and learning and consciousness.

For instance, studies of a number of nonhuman animals (especially chimpanzees, other apes, parrots, and dolphins) have indicated that these organisms can respond to complex stimulation, such as encoded queries and requests, in ways that resemble our own use of language

(Savage-Rumbaugh et al. 1998). Just as we routinely attribute consciousness and will to other people by empathy based on their behavior, we are inclined to attribute these capabilities to the subjects of these experiments. These studies are unusual among biological and psychological experiments in two ways: their small samples of subjects and their intensive involvement of humans (as opposed to experiments with many comparable subjects and largely mechanical interactions with them). The small sample is justified because the interest is in the potential rather than the norm of behavior. If one individual chimpanzee can converse like a human, that alone makes the point.

The lack of replication in combination with intensive human interactions with subjects raises further issues. Each of these studies has been conducted in one laboratory and directed by one principal investigator or a small team. No team has ever carefully replicated the procedures of any other. Nevertheless, there has been an accumulation of similar results with similar protocols, so that it is becoming more difficult to exercise broad skepticism about the kinds of responses evoked.

There is an even deeper controversy about language-like responses by nonhuman animals. Interpretations of these responses often devolve into a polarity between attributing the observed responses to no more than thorough (rote) learning as opposed to the spontaneity or creativity that human language seems to show (Lutz 2009). There are twin problems here – it is difficult to distinguish complicated from random patterns of responses, and it is also hard to distinguish repeated from rote responses. Infrequent, unprecedented, and unrepeated responses, just what we look for in consciousness, cannot be easily shown statistically to differ from accidental or random responses. On the other hand, statistically significant patterns of response require replicated results, which then come to resemble thoroughly learned or rote responses.

The issue of thorough learning, as opposed to volitional thought, is a pervasive problem in comparative studies of consciousness. Consider another example of convergence in mental abilities of human and nonhuman animals – abilities to respond to oneself in a mirror and to attribute

mental states to others (and by extension therefore to oneself). Responses to mirrors are no doubt tricky. Many animals respond to mirror images (itself a remarkable capability) as if the image were another individual of its species, perhaps a rival evoking aggression. Chimpanzees in contrast behave as if they see themselves in a mirror, for instance, by touching unexpected marks on their faces that they see only in a mirror. Such responses to mirrors, which seem normal to most humans nowadays, indicate a remarkable advance in mentality. Yet this ability clearly requires learning. Humans with no experience of mirrors or photographs of themselves, as anthropologists often report, do not easily recognize their images. And anyone can try the experiment of directing movements (or even identifying oneself) in a *mirror image of a mirror image* of yourself, an experience that reveals uncomfortably that mirrors require considerable practice to master. Even recent experiments in which chimpanzees without a direct line of sight can use a mirror to sign to a human recipient, but do so only when the recipient is looking at the mirror (Lurz et al. 2018), are subject to the same questions about thorough learning. Evidently humans nowadays master some superordinate associations involving mirrors that most nonhumans have not, but humans have not mastered all the possible associations. Nor is it easy to determine whether or not some nonhuman animals have comparable mastery (De Veer and van den Bos 1999).

Actions that result from rote learning raise another question about consciousness. Humans often master well-practiced tasks to the extent that they are performed unconsciously. Conspicuous examples are actions or sequences of actions performed routinely, such as making a cup of coffee each morning. Yet on any one occasion, the awareness of having performed an action can escape us, for instance, when we are perplexed about whether we had already added the sugar. Certain actions, swallowing and walking, for instance, consist of complex muscular coordinations that we are seldom aware of, although this lack of awareness can cause serious accidents.

Furthermore, this issue of the criteria of consciousness merges with the issue of private

sensations. How can we know, other than by imputations based on coarse empathy, what another organism feels or even senses? Introspection is the source of these insights. How can it be determined that another organism, other than myself, is conscious, acting by will rather than rote, in the same way I do?

Neurophysiology of Consciousness

An obvious possibility for recognizing consciousness is to investigate neural activity during presentations of stimulation. Neurobiologists can now detect in detail the neural events that result from sensory stimulation, both those sorts that we normally are aware of, for instance most exteroceptive sensation, and those we are normally not aware of, for instance most proprioceptive sensation. This approach can extend to neural events in the brain. Physiologists now know a great deal about local areas in the brain, even particular neurons, that are specialized for analyzing sensations, controlling muscles, generating emotions, consolidating memories, comprehending or producing language, even recognizing a visual pattern as a human face. Centers in the brains of nonhuman animals have similar functions (the centers for learning and producing songs by birds are particularly well documented). Is there such a center for consciousness?

Suggestive in this case is an experiment that seems to reveal a half-second or so delay between the initiation of a spontaneous action, on one hand, and awareness of it, on the other (Libet et al. 1983). Because action precedes awareness, it appears that action triggers awareness, rather than vice versa, so that consciousness is the effect of our actions rather than their cause. Volition becomes an illusion, and consciousness seems to be a distinct operation, a candidate for localization in the brain. Some qualifications are in order, though. Subjects record their awareness of the action by remembering the exact position of a spot moving rapidly around the face of a clock. Recording this visual stimulus in memory is itself a response to the spontaneous decision to act, just as much the act itself is a response to this decision.

Such an experiment thus does not necessarily reveal that action precedes volition. Instead each of these two operations requires different neural events lasting finite, and evidently not exactly equal, amounts of time. Furthermore, the memory is encoded in language, which becomes the sole means of obtaining the datum actually recorded by the experimenter. Again we are back to questioning how we can know what another organism feels or thinks, unless that organism tells us in some way.

The inability so far to find a locus in the human brain specialized for consciousness has led to proposals that awareness results from distributed networks of neural interactions. Computer programs for learning complicated tasks often employ “neural networks,” one or more intermediate layers of “cells” that reciprocally influence each other’s activity, between an input (sensory) layer that provides initial conditions and an output (motor) layer that represents the response. Further programming defines the utility of any response and uses this evaluation to regulate the stability or variability in the properties of cells in the intermediate layers. An arrangement that produces responses with low utility is thus allowed to change (mutate) before subsequent trials; those that lead to responses of high utility are stabilized (saved), in other words, learned. Although these computer programs are called “neural networks,” it is still not clear how closely they resemble operations in a brain. Only at a superficially general level can we suppose that distributed operations in the brain share the features of computational “neural networks.” The specifics of neural processing to produce consciousness remain as elusive as ever.

Continuity Between Brains and Other Machines

The relationship between consciousness and language arises in proposals to distinguish humans from other machines – or by extension to determine whether or not any machine is conscious. Turing’s test and Searle’s modification of it are examples (Dennett 1991; Searle 1997). Each

involves a judge posing problems to unseen contestants. The issue is whether a human (conscious) contestant can be distinguished reliably from a nonhuman (unconscious) one. Searle contends that Turing's test would not distinguish between a human who understood a language and one who just followed rules by rote. It thus could not distinguish a conscious human from an unconscious machine. By extension, it is worth emphasizing, it would also not distinguish between a conscious and an unconscious machine. A fundamental question here is whether or not conscious behavior, such as language, is strictly rule-following or not. And thus whether or not humans are strictly rule-following machines or not. We might also extend this question to whether or not machines do or do not strictly follow rules.

Noise as a Determinant of Consciousness

These conundrums about the relationships of volition, consciousness, and learned and unlearned behavior all intertwine with issues of language and even communication in general. Any evidence about an organism's consciousness depends largely, in the final analysis perhaps exclusively, on what it reveals in its behavior. The evolution of consciousness thus depends in a fundamental way on the evolution of communication. It is thus remarkable that noise influences the evolution of communication in a way that provides a straightforward explanation for the evolution of subjective experience (Wiley 2015).

Noise, as Claude Shannon first emphasized in his revolutionary analysis of information, is anything that results in errors by receivers during communication (Shannon and Weaver 1963). Noise can consist of extraneous irrelevant background stimulation that mixes with signals during transmission from signaler to receiver. This is what is commonly thought of as noise. Noise, in Shannon's sense of errors by receivers, can also result from degradation and attenuation of signals during transmission. It can also result from irregularities in a signaler's nervous system which introduce irregularities in its signals; and it can consist of analogous irregularities in a receiver's

nervous system which introduce irregularities in its perceptions. As a result of any of these sources of noise, a receiver's perception only imperfectly reflects a signaler's actual situation.

To apply this approach to the evolution of consciousness, note that the dilemma confronting a receiver of signals in communication is strictly analogous to that confronting a perceiver of external objects and events in general. Noise in perception can result from mixing of sensations from irrelevant sources, from degradation and attenuation of stimulation during transmission, and from unpredictability in a perceiver's own nervous system.

At the moment of perception, a perceiver has no way to determine whether or not the perception corresponds to a particular external situation or to an erroneous illusion. All the perceiver knows at the moment is its perception. Nevertheless, memory of repeated perceptions, especially in combination with communication with other individuals, could reveal these discrepancies. In this way such an organism, capable of thought and language, could develop a sense that its own perceptions differed, in some respects and on some occasions, from those of others. Both some ability for abstract thought (a capability for generalization and discrimination) and some ability for communication of such abstractions seem crucial for this awareness. Otherwise individuals would be isolated within the shell of their own perceptions. They might well learn to avoid or to prefer certain perceptions, but it would be difficult to compare them with other individuals'.

Because of noise in perception or communication, a perceiver or receiver must make a decision every time it acts on any sensation. It must decide whether the sensation warrants a response (and also which response). In other words, it must decide whether a sensation is a signal (with some relevance for the perceiver) or noise (with no, or misleading, relevance). Noise creates the unavoidable possibility of two incompatible kinds of errors in perception, false alarm or missed detection. All perceivers, even those organisms such as sponges or bacteria with no nervous system like ours, are perforce decision-makers.

Signal detection theory (Macmillan and Creelman 1991), based on Shannon's theory of

information, and decision theory allow a formal mathematical analysis of the performance of any perceiver in the presence of noise. Because of the two conflicting sources of error, a perceiver is in a double bind. It cannot reduce one source of error without increasing the other. As a consequence, it can only optimize its decision in particular circumstances and cannot attain perfect performance. This optimization leads to a fundamental conclusion that *perceivers cannot escape from noise*; their only option is to optimize their responses in each situation.

This is what organisms actually do. All must deal with unpredictable contingencies. Evolution by natural selection provides a mechanism that can optimize, within limits, neural capabilities to make decisions that promote survival and reproduction for the organism. In a fundamental way, nervous systems are decision-making organs devoted to this task of responding efficiently to conflicting possibilities of stimulation. Every organism must confront its subjectivity with some decisions, no matter how crude the mechanism.

Awareness of subjectivity in perception, however, requires a nervous system to form higher-order associations. When these connections between subjectivity and objectivity reach awareness, we can expect consciousness. The process requires a sufficiently complex nervous system. The logical inconsistency of self-reference might indicate that no such system can ever be completely aware of all its operations, even its degree of self-awareness.

Humans clearly have achieved the highest performance so far. Yet the evolution of this capability seems likely to have emerged gradually by successively more complex mental associations. Whether or not other organisms (great apes and bottle-nosed dolphins come to mind as possibilities) have reached states of consciousness comparable (although perhaps not identical) to those of humans and whether or not some future organism or some other deterministic machine might eventually reach higher levels of self-awareness are questions for the future. Perhaps humans have reached an adaptive peak in the evolution of consciousness, so further advances might require brains evolved in a new anatomical/physiological direction.

Conclusion

The mathematical analysis of optimal behavior in noisy situations thus indicates that (1) noise is an inescapable component of communication, (2) subjective awareness of self is a higher-order association of perceptions and responses, (3) decision-making is fundamental component of all communication and perception, and (4) both processes are as unpredictable as the unavoidable noise. An advantage of this analysis of the evolution of communication in noise is the framework it provides for addressing the questions posed at the start of this essay.

To account for the source and the content of self-awareness, previous discussion has always relied either on supernatural intervention or on vague neural operations on purified sensations. Supernatural intervention of course obviates any mechanistic explanation, including evolution. Response to pure sensations, on the other hand, leaves each organism encased in its own perceptions, without a way to distinguish between subjective and objective events. The evolution of noisy communication, in contrast, shows that self-awareness (consciousness) results directly from the operations of nervous systems exposed to noisy sensations. We can expect that the neural correlates of self-awareness will depend not only on sensations of interest to an organism but also on the noise mixed with them. The resulting explanation for self-awareness requires no unnatural or unspecified components.

The principal conclusion from such an analysis is that the problems of consciousness might reduce to problems of evolution, signal detection, and neurobiology, all highly mathematical and physical, and thus mature scientific fields. Discussion of the mechanisms of consciousness might therefore migrate from philosophical to scientific discourse.

Adaptations; Changes in adaptation expression; Evolution; Natural selection

Definition

Adaptations, characteristics that enhance the survival and/or the reproductive success of an organism, change their means of expression over time.

Introduction

Like organisms, adaptations evolve. Adaptations vary from physical characteristics and traits, such as gills, hair, organs, etc., to behaviors that aid the survival and reproductive success of an organism. Although an organism's physical features have been the exemplar of adaptations, behavioral and mental features as evolutionary adaptations are now under scientific scrutiny. Today, the field of *evolutionary psychology* takes initiative to shed light on human psychological adaptations despite that Charles Darwin, discoverer of biological evolution via natural selection, depicted the relationship between physical and mental adaptations back in 1859.

Evolution: Change over Time

Since evolution's inception, the term has been recklessly connoted with biological evolution via natural selection. Although biological evolution is a representative of evolution, it is not the only one. *Evolution* is a general word for *change over time*, and it is widely accepted that nothing remains uniform forever; therefore, everything changes when given the sources to. Adaptation expression is malleable.

Physical features that enable an organism to adapt to its environment are unlikely to have always been adaptive. For example, the human bellybutton and the appendix are not considered to be *adaptive*. Moreover, the appendix could even be considered maladaptive when it precipitates appendicitis. When a physical or mental feature is a *mismatch* or when it does not align with an organism's ability to adapt to its environments, it may be considered as a neutral or maladaptive trait (Geher 2014).

The expression of adaptations is subject to evolution. It is parochial to reduce the expression

of adaptations to only physical or biological properties. Actions and behaviors that practice, utilize, or enhance an organism's biological traits and abilities produce an advantage over others that do not.

Biological Adaptations

Biological adaptations are physical features that facilitate the survival and/or the reproduction of an organism. The loose and attached jawbones in some snakes, for example, permit them to devour prey larger than their bodies (Futuyma 2009). Some scientists suggest that human body height evolved for thermoregulation in hotter environments, locomotion and flexibility, and mobility (Migliano and Guillon 2012).

A more recently discovered human biological adaptation is pregnancy sickness in women, sometimes referred to as morning sickness. The healthy development of the fetus becomes at risk when exposed to toxins and pathogens within the mother. During the first trimester, pregnant women commonly experience nausea and vomiting. Regurgitation of potentially harmful foods is reckoned as a biological adaptation (McElroy and Townsend 2015).

Evidence of Psychological Adaptations as Evolved Adaptation Expressions

In *The Origin of Species* (1859), Darwin concluded that “psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation,” which was one of the first positions that mental qualities are also adaptations. *Psychological adaptations* are generally considered to be the results of biological adaptations, according to evolutionary psychologists. Every action, belief, and thought relates to the neural circuits and chemicals that constitute the mind (Cosmides and Tooby 2000).

Ants display extraordinary demonstrations of altruism, the selfless acts for others. Rather than solitarily seeking routes to travel across dangerous

obstacles, such as water, ants will cling on to each other in order to create a bridge molded of their living bodies for themselves to cross (Futuyma 2009). Instead of evolving a physical trait like wings to fly, ants acquired inherent tendencies that take advantage of their physical size to prevent water from penetrating their *living bridge*.

Numerous evolutionary scientists consider instincts to be the foundation of psychological adaptations. Distinguished emotions in humans like fear, anger, jealousy, and happiness may have been acquired due to the pressures encountered in one's evolutionary history. Leda Cosmides and John Tooby (2000) posit that each emotion is elicited by different and specific circumstances. For example, fear when crossing a bridge hundreds of feet above land is a psychological adaptation to demotivate one from being too indolent and audacious while crossing.

Other evolutionary psychologists posit that cognition skills derived from the cerebral cortex gave rise to human's cultural cornerstone, language. Linguistic skills would enable the prehistoric humans to socialize and communicate vital information. Increased efficiency in communication and socialization is believed to have contributed to the larger band size that early *Homo sapiens* or modern humans lived within (Harari 2015).

Higher cognitive function is also theorized to have given rise to *cheater-detection* and *mate selection*. Cosmides and Tooby (2000) accounted how critical it would be in a society of social humans to be weary of those who lie and act as *free riders* to obtain resources unjustly. The psychological adaptation of an enhanced memory for faces of cheaters over non-cheaters deploys pre-existing biological features in the brain for facial perception and memory.

Mate selection is considered by evolutionary psychologists to be a critical evolutionary deed. Relative to most animals in the animal kingdom, *Homo sapiens* are selective as to whom they copulate with. Selecting a partner who exhibits qualities of poor parenting could be detrimental to a helpless and premature child. Allan et al. (2012) found that heterosexual women have significantly better memory for more masculine faces of men

than less masculine ones. Masculine facial features are a proxy of testosterone, a sex hormone that is associated with immunosuppressant effects, which would signal higher genetic quality in a mate. Like cheater-detection, the biological traits in the brain that enhance memory for particular individuals serve as a new means of expression of an evolutionary adaptation.

Conclusion

Evolution strictly means *change* and that everything is subject to change. Adaptations described by evolutionary biologists ranging back to Darwin are no exception to this postulate. An organism's physical characteristics have been gradually molded into adaptive, neutral, or maladaptive traits that increase in efficacy when synchronized with instincts or behavioral traits. It is necessary for scientists to properly construe what an *adaptation* truly is and how it can be expressed in all living specimens. It is fortunate that evolutionary psychological science stands at the forefront of the investigations of psychological adaptations. After all, what it means to be human is the product of these evolved adaptations.

The evolution of the mammalian ear and understanding of sound.

Introduction

In order to better comprehend the evolution of ear perception, one must understand how sound is conducted until it reaches the ear. Environmental changes have imposed a need for the mammalian ear to evolve in order to enhance the survival of species. Several researchers have attempted and succeeded to unlock the evolutionary mystery and history of the mammalian auditory system and perception.

Distinguishing the Direction of Sounds

To understand the direction of sounds, we need to understand how sound is conducted. Usually, sound is created when an object is vibrated. The vibration travels through the surrounding medium, which is usually air, as pattern of changes in pressure which eventually is heard as sound (Moore 2001). Sound is called a pressure wave for the reason that when the molecules of the ear come closer, the pressure increases resulting in a process called compression; when the molecules move further apart, the pressure decreases resulting in a process called rarefaction (Oghalai and Brownell 2012). According to a theorem by Fourier, the sound could be described in sinusoids, which is an analysis of complex waveforms. A sinusoid resembles the sound produced by a tuning fork, which is often called a simple tone, or a pure tone. Each sinusoid is called a Fourier component of the sound and a magnitude plot of the components as a function of frequency is called a spectrum. The result of a Fourier analysis is to produce the spectrum of the soundwaves by splitting the waveforms into component sine waves of different frequencies (Moore 2001; Pickles 2012). There are two important variables in each sound wave, the frequency and the amplitude or intensity (loudness). Frequency is the number of waves that passes a point in a second and is measured in cycles per second, otherwise called hertz (Hz). The amplitude or intensity is related to the magnitude of the produced movements, and is measured in decibels. The traveling sound wave relies upon the

pressure of the environment which is the medium in order for the sound to be heard. This is called impedance of the medium. If the impedance is high, high pressures are needed to yield a definite velocity (see Pickles 2012, pp. 1–19).

The very first step of the hearing process is when the outer ear captures the sound waves which travel to the eardrum and cause it to vibrate. In the middle ear, the ear bones convert the air-borne vibrations of the eardrum into fluid-borne vibrations in the cochlea. The traveling wave is then converted into bioelectric signals in the auditory sense cells of the inner ear (Hoy 2012).

The sound is then analyzed in the inner ear, which is responsible for performing spectral and temporal analyses of the acoustic signal. The spectral analysis is the process of extracting and defining the various frequency components of the acoustic signal. Frequency and intensity is what is otherwise called “pitch” and “loudness.” The cochlea is responsible to tease out the frequency components of the incoming acoustic signal and determine its amplitude and the temporal aspects of it. This process is the first level of auditory processing; subsequent processing takes place in the auditory pathway to the brain (Seikel et al. 2010).

Since sound is a disturbance in the air, this causes the tympanic membrane (TM) to move. The movement, afterwards, is translated to the oval window where, based on the movement of the TM (inwards or outwards), the stapes footplate is moved accordingly. More specifically, when the stapes compresses the perilymph of the scala vestibuli, Reissner’s membrane is inflated toward the scala tympani. That is, when the fluid of the scala vestibuli is compressed, it is translated directly to the basilar membrane. In the structures of the TM-ossicle-footplate, the sound – translated into Hertz – creates a 100 Hz signal in the footplate, which in turn creates a periodic vibration to the basilar membrane where a traveling wave is initiated (Seikel et al. 2010).

The Basilar Membrane

The way the sound is distinguished depends upon the frequency of the acoustic signal. High

frequency sounds cause vibration of the basilar membrane closer to the vestibule, which is the basal end of the cochlea. Low frequency sounds result in a long traveling wave that reaches the apex, having to do more distance along the basilar membrane. Hence, the traveling wave distinguishes the frequency components of complex sounds because the higher frequency sounds are processed in basal regions, whereas lower frequency sounds are processed near the apex. The analysis and discrimination of lower to higher frequencies is credited to the basilar membrane. This was demonstrated on a series of experiments, performed by von Békésy (1948), that the elasticity of the basilar membrane is reduced towards the stapes rather than the helicotrema, consequently producing a stiffness gradient which, when the cochlea is stimulated, results in the creation of a pressure wave that travels from the base to the apex (Gelfand 2010, p. 75). Regardless of how the traveling wave is initiated, it always travels from the base of the basilar membrane towards its apex based on the certain gradient of the membrane (Seikel et al. 2010).

Binaural Hearing

In regards to sound localization, it is through the process of binaural hearing that performance is improved in auditory tasks. Specifically, an essential task for the central auditory pathways is to analyze the auditory messages sent by the two cochleae into the auditory structures of the brain. This segregation and localization of the sound messages is significant for the separation of target signals from noisy environments. For example, sound coming from a source on the right reaches the left later than the right ear – because it has to travel further – and it reaches it with a lower intensity. This is called the head shadow effect, that is, the further to the right the source is located, the larger the interaural differences (Avan et al. 2015). Binaural interaction takes place mainly and almost simultaneously at three levels of the brain: the superior olivary complex (SOC), the nuclei of the lateral lemniscus (NLL), and the inferior colliculus

(IC) (for more on the binaural pathways of the brain see Moore (1991)).

There is an evolutionary advantage of binaural processing of sounds. Information gained from this process could help detecting a predator approaching surreptitiously while the prey is engaging in a certain activity, that is, drinking water around a noisy environment. This way, the brain, by evolving and developing a refined stereophonic sound system, has contributed in the survival of species (Avan et al. 2015). Although for humans survival may not be at stake, binaural processing is helpful along noisy environments such as cocktail parties, where the listening ability depends on the type, number, and location of interfering sounds as well as the interactions of them (see Hawley et al. 2004). It is noteworthy that the increase in brain size of mammals is probably due to an increased processing ability for binaural sounds in various auditory nuclei in the brain in order to deduce the locality of sound (Manley 2010).

Reichert-Gaupp Theory

Karl Bogislaus Reichert and Ernst Gaupp created a theory regarding the origin of mammalian ossicles of the ear. To be more precise, Reichert established the relationship between the reptilian jaw bones and mammalian middle ear bones in 1837 which was later taken and perfected by Gaupp (World Heritage Encyclopedia 2017). What is hypothesized is that the malleus and incus are products of the first curves of the skeletal elements of the middle ear (Takechi and Shigeru 2010). Moreover, the stapes, incus, and malleus have been confirmed to be homologous of the reptilian columella auris, quadrate, and articular (Westoll 1944). What is notable is that this theory was established before Darwin's *Origins of Species* (Takechi and Shigeru 2010). It is, also, noteworthy that Ernst Gaupp was the first to present a synthesis of embryological and paleontological data to explain the evolution of the mammalian middle ear structures (for a historical review of the Reichert-Gaupp Theory see Maier and Ruf 2016).

Evolution of the Mammalian Ear

Regarding the evolution of the mammalian ear, Masterton et al. (1968) were set to classify historical changes in human hearing by comparing it to the hearing of the mammalian evolution. What was found is that high frequency hearing (more than 32 kHz) is a mammalian trait due to the short space between their ears, and that there is a natural selection for specific sound localization. However, sounds in the lower frequency spectrum (less than 1kHz) is mostly a characteristic of the human species.

Moreover, Manley (2017) has provided an elaborative description concerning the mammalian ear evolution. His thesis is that more than 250 million years ago (Paleozoic era) the synapsids were parted from the stem reptiles resulting in the creation of the mammalian species line. During the early stages of the Mesozoic era, the mammalian ancestors had a “temporary” middle ear that was connected to the lower jaw which was later developed to a “definite” middle ear. The organ of Corti was also formed during this period (Manley 2017).

The bone integration into the cochlea was shaped only in therian mammals and came before the cochlear coiling and the partition of Eutheria from the Metatheria. The coiling in the Cochlea resulted in the loss of the lagenar macula and, subsequently, the evolution of prestins, a motor-protein found in high concentration in the lateral cell membranes of outer hair cells that is significant for an increased sensitivity at low sound levels (for more about Prestin see Dallos 2008; Li et al. 2010; Zheng et al. 2002, 2000). The hair cells are responsible for cochlear amplification and rapid cell length changes (Franchini and Elgoyhen 2006), the transduction of mechanical activity into electrochemical activity when the stereocilia are bent (Gelfand 2010, p.76), and the compensation for the energy loss for the transmission of the traveling wave on the basilar membrane resulting in an increased sensitivity of the ear (as much as 50 dB) and an increased frequency selectivity at low intensities (Moller 2013, p. 55). According to Franchini and Elgoyhen, prestin evolved in mammals that lead to the development

of the cochlea. They also have found evidence for the positive selection in the motor-protein prestin only in the mammalian lineage.

Additionally, signatures of positive selection on the $\alpha 10$ were found, but not on the $\alpha 9$, nicotinic cholinergic receptor (nAChR) subunits (Franchini and Elgoyhen 2006). According to Franchini and Elgoyhen, the $\alpha 9\alpha 10$ -containing nicotinic cholinergic receptor plays a significant role in various physiological processes. For instance, $\alpha 9$ is required for the normal development of the efferent synapses in the inner ear, and they serve as the unique source of extracellular calcium for Ca^{2+} -activated potassium channels in mature auditory hair cells (Vazquez 2016). Franchini and Elgoyhen suggested that evolutionary changes of the $\alpha 10$ subunit most probably allowed the $\alpha 9\alpha 10$ heteromeric receptor to contribute to the function of the mammalian cochlea.

The discovery made by Montealegre-z et al. (2012) is worthy to note. The researchers postulated that there is a similarity in the hearing system between mammals and rainforest katydids. Specifically, these insects demonstrated to possess equivalent biophysical mechanisms for the processing of sounds as such of mammals, based on the three stages of collecting sound from the outer towards the inner ear. Hoy (2012) noted that these three stages are likely to have developed predominantly in insects and much later in mammals.

Conclusion

To better understand how auditory perception was evolved, one must understand how sound firstly generated. First of all, sound is generated by a pressure disturbance in the atmosphere, where sound measured in both frequency and intensity travels in wavelengths to the ears of the listener. The sound is then captured by the outer ear, and travels from the middle ear to the inner ear for processing. There have been theories of the evolution of the structures of the ear, starting from the Reichert-Gaupp Theory, who are credited with the discovery of the mammalian ossicles of the ear. Other researchers have, also, contributed to the discovery of the mammalian ear evolution.

[Evolution of signaling and responding](#)

Definition

Evolution of responses by a receiver to signals from a signaler.

Introduction

Understanding the evolution of communication has undergone several saltations in the past century. Nonhuman animals are now routinely recognized to have spectacular and complex forms of communication. Also, after decades of controversy, it is now clear that communication is a form of cooperation. The conditions for the evolution of cooperation have also become clear. All of these statements can no doubt still excite controversy, but beyond any contention, they raise issues for the evolution of human language, as an extreme case of complexity in communication.

This article summarizes developments in evolutionary biology relevant to communication in general and introduces some implications for the specific case of language. Another article, *Design Features of Language*, develops these implications in detail.

Comparative Study of Signaling

Study of communication by animals other than humans began in earnest with Darwin. Earlier concepts had placed organisms on an immutable *scala naturae*, with progressive elaboration of capabilities, including mental capabilities, from lower to higher, with a culmination among sublunary creatures in humans. Linnaeus' *Systema Naturae* instead formalized hierarchical classification of organisms, although humans still occupied first place with the unique attribute of wisdom.

Darwin first introduced natural selection of behavior in *On the Origin of Species* (1859), elaborated the possibilities in *The Descent of Man, and Selection in Relation to Sex* (1871), and illustrated applications to communication in *The Expression of the Emotions in Man and Animals* (1872). In subsequent decades, the study of animal behavior diverged into several paths: (1) experimental study of learning in a few convenient species, (2) experimental study of the sensory capabilities of animals, and (3) observational study of diverse organisms engaged in natural behavior. The first path quickly established unsuspected capabilities for learning in animals

and then investigated these abilities in species amenable to experimentation. The second path revealed that many animals had unsuspected sensory capabilities, including some unavailable to humans, such as complex vision, including ultraviolet and polarized light, ultrasonic sound, electric and magnetic fields, and echolocation. Mental capabilities of animals were no longer just subsets of human capabilities. The third path, close observational study of animals, was at first pursued on the fringes of academic science. It eventually established at least six points important for a comparative study of communication.

1. Many animals have sizable repertoires of actions, including vocalizations, not directly related to nutrition, survival, or procreation. Often they are relatively conspicuous, discrete, and stereotyped. The term "display" was appropriate for them.
2. These displays are usually deployed in interactions between individuals and often evoke appropriate responses. They thus fit a basic criterion for communication. Furthermore, this communication is mostly among conspecific individuals. Both displays and responses are usually species-specific.
3. The structural and behavioral traits of these displays reflect the phylogeny of species. Indeed, for a while it seemed that comparisons of these displays might reveal phylogeny better than morphology could. They appeared to have evolved in arbitrary directions, without the complications of convergent adaptations. Yet their stereotypy and elaboration (called ritualization) suggested adaptations for communication (Cullen 1966), and eventually it became clear that displays include many adaptations to their environments and their functions in communication (Wilson 1965; Wiley and Richards 1982; Endler 1992).
4. Detailed comparisons of behavior between and within species suggest that displays have often evolved by elaboration of much simpler actions, either actions for individual maintenance, incipient actions in other contexts, or actions that seemed partially inhibited or redirected in the circumstances (Tinbergen 1952, 1960).

5. Experiments show that animals often respond only to a few simple features of displays (Tinbergen 1951). These “sign stimuli” often elicit relatively stereotyped responses, a finding that provided opportunities for a comparative neurobiology of behavior.
6. The ontogenetic development of these displays and their corresponding responses often does not depend on shaping by reinforcement or encountering models. In other words, they are in many cases “innate” or relatively canalized, in the sense that they develop in a stable way despite normal variation in individuals’ experiences. In contrast, other actions and responses, equally complex and stereotyped, are learned by experience. In some cases, perhaps always, this learning is subject to constraints, predispositions such as sensitive periods, or templates. The first such case was imprinting of the following response by newly hatched precocial birds. Another was imitation of species-typical patterns of singing by songbirds. Predispositions in these cases are more canalized, within normal variation of experience, and simpler than the subsequent learned displays or responses. These examples of constrained learning have become epitomes of the interaction of genes and environment in the evolution of behavior, in particular, communicative behavior (Bateson 1981; Marler and Peters 1977; Marler 1990; Soha and Marler 2001a, b).

The discovery of such widespread and complex communicatory behavior in animals, generated by nonintuitive developmental processes and enmeshed in diverse social interactions, raised many questions about its evolution.

Evolution of Honesty

Until 50 or so years ago, the evolution of societies was explained by cooperation among individuals. Because cooperation is mutually beneficial, the action of natural selection in promoting cooperation seemed easily understood. This naïve attitude was overturned by George Williams’ *Adaptation*

and *Natural Selection* (1966) and Richard Dawkins’ *The Selfish Gene* (1976). In the first place, not all individuals in an ostensibly cooperative society benefit equally. Individuals, for instance, might reduce their exposure to predators by herding, but those near the outside of a herd have more exposure than those in the center. Williams and Dawkins emphasized that, if differences in individuals’ social behavior are associated with differences in the genes they carry, any allele (variants of genes) associated with behavior contributing to greater survival and reproduction spreads in a population, while others do not. Thus an explanation for the evolution of social behavior by natural selection requires an analysis of how each individual’s behavior in social interactions affects its reproduction and survival.

This sort of argument provokes questions about how the behavior (or any trait) of an individual is related to its alleles. This basic process of behavioral ontogeny is revealed especially clearly in the studies of constrained learning in animals. An individual’s development involves an interaction, in the statistical sense, of its genes and environment throughout the course of its life. As a result, genes do not determine anything about an individual’s development, but they influence all of it. The same is true of the individual’s environmental experiences. Natural selection results from differences in the reproduction and survival of individuals, whose traits are thus influenced more or less, in one way or another, by their alleles.

An early application of this principle was the evolution of polygynous mating systems, those in which most females mate with a few males. An argument that successful males benefit from multiple matings is insufficient without an explanation for how females benefit. The “polygyny threshold hypothesis” proposed that in habitats with high spatial variability (for instance, grasslands and marshes, where many nesting birds have polygynous mating systems), a female could compensate for reduced parental help from a polygynous mate provided that her mate’s territory provided access to more food and safer nesting sites (Orians 1969; Searcy and Yasukawa 1995). This new approach to the evolution of

social behavior set the stage for a reassessment of the evolution of communication.

Communication often involves individuals in asymmetrical roles, males enticing female mates, opponents in aggressive encounters, and competitors for food or space. Mutual advantages or cooperation in communication is less clear in cases like these, in which one individual might benefit by deceiving the other about its strength or suitability. Honesty, in contrast, would require a benefit for an individual responding to a signal as well as a benefit for the sender. Dawkins and Krebs (1978) suggested that signals are usually not honest. Instead they manipulate receivers for the signaler's advantage, despite the receiver's disadvantage. They deceive rather than inform receivers. Alternatively, Zahavi (1975, 1999) suggested that receivers avoid this problem by responding only to costly signals, because only costly signals are honest.

Zahavi's original proposal included two specific conditions for honesty: (1) costs of signals must be wanton (more than necessary); and (2) signals must have a form that impacts the attribute that is of interest to a receiver. The first of these conditions separates the costs of producing signals into a necessary component, which assures detection by a receiver, and an excessive or "wanton" component, which ensures honesty. The second condition requires that a signal interferes with its own meaning, in the sense that it must compromise the condition of the signaler that interests the receiver. For instance, a signal indicating efficiency in collecting food might partially compromise an ability to find food; or one indicating skill at avoiding predators would partially increase a signaler's vulnerability, for instance, by attracting a predator's attention or approaching and perhaps taunting predators. Such a signal would assure a receiver that the signaler was good enough at the particular task to overcome the handicap. For these reasons, Zahavi stipulated that the "wanton" costs of signals are handicaps. Handicaps thus became conditions for cooperative communication in which both signaler and receiver benefited.

This handicap principle became a central tenet of the study of animal communication, primarily

as a result of mathematical demonstrations that honesty in signaling required costs for signals. Grafen (1990a, b) and Maynard Smith (1991) used different approaches to show that (1) the cost of an honest signal must exceed 0 as a general rule but (2) the cost to the signaler or the benefit to the receiver could equal 0 when signalers were genealogically related to receivers. Maynard Smith and Harper (2004) nevertheless concluded that the costs for honesty must exceed a cost necessary to avoid ambiguity in communication. Many studies in the past three decades have demonstrated that signals are usually honest (receivers' responses have benefits in terms of survival or reproduction or have some correlated effect) and that signals have costs related to survival or reproduction (Searcy and Nowicki 2005).

The handicap principle, however, is vitiated by two problems (Wiley 2015, 2017; see also Getty 1998; Számádó 2011). (1) The mathematical analyses make no distinction between necessary and excessive costs and in fact demonstrate only that honesty requires signals with costs >0 . It is difficult, perhaps impossible, to imagine a signal that has no costs whatsoever, in terms of energy, risks, time, or lost opportunities, any of which would affect survival or reproduction. These analyses thus make no predictions about how much cost honesty requires. (2) An analysis of the optimization of communication in the presence of noise (Wiley 2015) shows that there is no distinction between costs of signals that reduce ambiguity and those that do not. During joint optimization of signalers and receivers in the presence of noise, all costs are incurred in reducing errors by receivers. Furthermore, a distinction between manipulation and information in communication is misleading, once information is more clearly defined, as proposed below.

More important, Grafen's calculations confirmed, although without much emphasis, that receivers must benefit from their responses to signals, at least on average. If receivers incur net costs for responding to a signal, then these responses do not evolve, and thus the signals do not either. The same conclusion applies to responses to signals from potential mates, although in this case, a receiver's benefits from

choosing a mate can include genes that influence survival and reproduction of the receiver's offspring (Pomiankowski 1987).

The principal conclusion of these analyses is thus not that honest signals must have costs but that both signaler and receiver must benefit from the responses. It is not necessary that every instance of a response to a signal has benefits. Instead, responses to signals must have benefits, on average, either immediate or delayed, for both signaler and receiver. Communication is indeed a form of cooperation, in which both parties do better on average by communicating than they can otherwise.

Evolution of Cooperation

Cooperation begins by one individual helping another at some cost to itself. The first step is thus an act of altruism, one that benefits another at a cost to the actor, with benefit and cost ultimately in terms of survival and reproduction. Helping, including signaling, fits this pattern. Alleles cannot spread in a population unless the individuals that carry them survive and reproduce more effectively than others. Consequently, the challenge is to determine how alleles for helping can spread when helping individuals incur net disadvantages in survival or reproduction. It turns out that altruistic *individuals*, for which helping others decreases their own reproduction or survival, can persist in a population. Nevertheless, "altruistic" *alleles*, for which association with helping decreases their frequency, inevitably disappear from a population. To reconcile altruistic individuals with selfish alleles, two possibilities are now recognized: (1) helping genealogical relatives or (2) receiving compensating benefits in the future.

The first occurs, for instance, when individuals help to raise a relative's offspring while not themselves reproducing. The example of honeybees, which had perplexed Darwin, is such a case. Somewhat similar cases have now been studied in scores of birds and mammals as well as numerous social insects (Koenig and Dickinson 2004; Bourke 2011). In many cases the helpers

(or workers) in fact reproduce to some extent either concurrently or later in life. Nevertheless, in some cases, such as honeybee workers helping queens to reproduce, the helping individuals almost never reproduce as much as the individuals they help. William Hamilton (1964, 1970) showed that alleles of individuals with lower chances of reproduction could nevertheless spread in a population provided these individuals helped close genealogical relatives. Close relatives can have a copy of any allele associated with a helper's behavior, as a result of their descent from a recent common ancestor. This "kin selection" is thus a special case of natural selection. If individuals sacrifice their lives to save the lives of more than two siblings (or more than eight cousins), any allele associated with this behavior would spread. The condition for the spread of an allele associated with helping is $C < rB$, where C is the cost in survival or reproduction for the actor, B is the benefit for the recipient, and r is the coefficient of genealogical relatedness of the actor to the recipient (one-half for a sibling, one-eighth for a cousin). Recent debate has clarified this possibility (Nowak et al. 2010; Abbot et al. 2011).

These ideas were quickly applied to mammals and especially to birds in which breeding pairs often have several helpers that feed or protect their young but do not (or are less likely to) reproduce. The evidence indicates that in most such cases, kin selection cannot provide a sufficient explanation for helping. Nevertheless, in the preponderance of cases, helpers are closely related to breeders. Kin selection in such cases contributes to the spread of alleles for helping even if it does not completely explain it. These principles apply to communication. We can expect individuals to accept uncompensated costs for signals or responses if the condition above is met.

The second case, when helpers receive later benefits, could apply to genealogical relatives and thus augment kin selection for alleles associated with helping. It might also apply to individuals without close genealogical relatedness. One possibility for later benefits is reciprocation: do unto your neighbor as you would have (or at least can expect) your neighbor to do unto you. Reciprocation though has its complications. Just because an individual helps another does not assure that the

recipient will return the favor. In addition to inevitable random contingencies, a population could plausibly include individuals with alleles associated with accepting help but never reciprocating, in other words defectors or cheaters. The possibility for cheaters in an otherwise cooperative population is pervasive. Close attention to cases of helping reveals that reciprocation is not a physical necessity, so there is always the possibility of a mutant allele that predisposes individuals to cheat by skipping reciprocation. In any instance of helping, the recipient is always possibly a cheater and the helper possibly a sucker.

In communication, the norm is honesty, but the possibility of exploitation, in other words cheating, is always present, both for signalers and receivers. On average a signaler benefits from responses by appropriate receivers, but there is always the chance of an inappropriate receiver, such as an eavesdropping rival, predator, or parasite. These inappropriate receivers exploit the signals intended for appropriate receivers. This situation is the converse of deception. In deception, an inappropriate signaler exploits the responses intended for appropriate signalers. There is always the possibility that a signaler or a receiver is a cheater in normally honest communication, and there is always the possibility that a signaler or a receiver is a sucker.

The usual recourse for analyzing the evolution of reciprocation has been game theory. In particular, the prisoner's dilemma and many related games have provided a foundation for mathematical and experimental analysis of the evolution of cooperation. An early discovery was that the behavioral strategy of iterated tit for tat permits the evolution of cooperation by reciprocation (Axelrod and Hamilton 1981; Axelrod 1984). This strategy consists of helping any new partner on the first encounter and then on subsequent encounters, either helping or not depending on whether or not the partner has reciprocated (Axelrod and Hamilton 1981; Axelrod 1984). It is a practical variant of the golden rule: do unto each partner as you expect that partner to do unto you.

Many additional possibilities for the evolution of altruistic behavior have by now surfaced. For

instance, altruistic behavior can evolve in local populations of sessile organisms, when individuals interact repeatedly with the same few partners as a result of their immobility. With the strategy win-stay-lose-shift, individuals help in their first interaction (or in random occasional interactions) and then help subsequent partners or not, regardless of whom they might be, depending on whether or not the previous partner reciprocated. In this case individuals do not keep record of their partners. Individuals might also develop a positive reputation for helping so that others would help them in the expectation that they would receive help in return. In this case, however, an individual's tendency to help would have to extend indiscriminately to other individuals. Alternatively individuals might develop a negative reputation so that others would have no expectation of reciprocation and thus refuse to help them. Finally, helpers might punish (impose extra cost on) defectors. In this case, helpers would themselves incur an additional cost for administering punishment. If the cost to each punisher was sufficiently small (perhaps shared among many helpers) and the cost to each punished non-reciprocator was sufficiently large (perhaps execution or banishment with little chance of survival or reproduction), this possibility could overturn the advantages of cheating but preserve most of the advantages of helping. Sharing the costs of punishment would, however, be another form of reciprocation, which would itself open opportunities for cheating (for instance, avoiding a fair share of taxes for policing). Sometimes cases of social approval or social disapproval are combined as contrasting examples of "social selection." All of these possibilities, when appropriate conditions are met, can explain how alleles associated with altruistic action can persist or spread in a population (Nowak 2006; for an example of punishment by monkeys, Hauser 1992).

There is one situation that does not allow such altruistic alleles to spread – badges identifying altruists. Altruistic individuals could increase the chances of reciprocation by recognizing each other by some badge associated with helping.

Richard Dawkins labeled this possibility a “green-beard effect” (on the possibility that green beards might serve for such a badge). The problem is that a shared badge just creates another opening for cheaters, individuals that sport the badge but do not reciprocate. Alleles with pleiotropic effects might work temporarily but only until a mutation broke the association between helping and development of a badge.

From decades of discussion, two conditions have emerged that always increase chances for the evolution of mutual helping: (1) genealogical relatedness between actors and recipients and (2) cognitive abilities for remembering interactions with individual opponents. Genealogical relatedness promotes the evolution of cooperation even when it does not provide a complete explanation. Memory of individual opponents is a crucial part of some options for the evolution of cooperation by reciprocity, such as tit for tat. Some options, such as tracking individuals’ reputations, require extensive memory of individuals. Nevertheless, even possibilities that require no memory of opponents, such as sessile neighborhoods or win-stay-lose shift, are even more likely to evolve reciprocity when memory of individual opponents is possible.

These possibilities for multiple contributing factors in the evolution of cooperation are often overlooked, because theoretical models have tended to take two directions, either focusing on the minimal conditions or on the maximal potential for cooperation. Those studying humans focus on the maximal possibilities for cooperation. Those studying other animals tend to focus on the minimal requirements for cooperation. Studies with humans in mind often assume complex cognitive capabilities without much comment and ignore the synergistic contribution of genealogical relatedness. They also can ignore the possibility that collaboration in a complex society, which results in unequal or uncertain advantages for individuals, generates natural selection for defection and for nothing-to-lose retaliation when disadvantaged. All these conditions for the evolution of cooperation apply to the evolution of communication.

Evolution of Individual Recognition

For the evolution of cooperation, all but the simplest possibilities rely on individuals’ abilities to remember other individuals and to associate them with particular patterns of behavior. This ability requires at least minimal object constancy for another individual, discrimination of that individual from others, and association of that individual in memory with its previous behavior. Object constancy, discrimination, and association are mental processes, perhaps each some aspect of association in general, that recur in all discrimination learning.

Abilities of this sort are now well documented for many nonhuman organisms. There are important distinctions to be made about the complexity of recognition (Wiley 2013a). First, the specificity of individual recognition can vary. An experiment might reveal that subjects respond to a neighbor or a partner (or often just to some features of such an individual) in a different way than to other individuals. Such a discrimination could result solely from habituation to repeated experience with a familiar individual. It would thus constitute recognition of a particular individual only when no other individual could have such familiarity. In some cases it is still not clear whether or not animals recognize territorial neighbors, parents, offspring, or relatives as individuals or as small sets of familiar individuals and whether or not these small sets are distinguished from others by associative learning or solely by habituation. On the other hand, experiments have shown that many territorial birds, for instance, can identify specific individuals within the small sets of their familiar neighbors.

Specificity of individual recognition is crucial for the evolution of cooperation. Only when specific individuals are recognized can interactions with possible cheaters be avoided or reduced. One report of a nonhuman animal that fits the requirements for tit for tat provides an example. A warbler in eastern North American forests can use its ability to recognize individual territorial neighbors in order to cooperate with them once mutual boundaries are settled. Experiments

with playbacks of songs show that they use tit for tat to retaliate specifically against defecting (trespassing) neighbors (Godard 1993).

The multiplicity of individual recognition can also vary, from recognition of a single other individual (for instance, a mate) to recognition of individuals in a small set (perhaps territorial neighbors, a small group, or current offspring) to recognition of potentially large numbers of individuals (as do humans). Some territorial birds are known to recognize several individual territorial neighbors, and primates (and presumably some other social birds and mammals) can recognize multiple individuals within their social groups and in nearby groups as well (Cheney and Seyfarth 1990, 2007). Associations with these individuals are probably not complicated in the case of territorial neighbors in particular locations but are possibly more complex in the case of group members encountered in diverse contexts.

Humans recognize large numbers of individuals with different degrees of specificity and different complexities of associations. There is a considerable literature on the influence of features, relationships of features, and contexts in peoples' abilities to recognize faces, but almost nothing is known about how many individuals a person can recognize nor about the cognitive complexities of how a person organizes these memories. This gap in our knowledge is surprising, because the memory, associations, categories, and relationships involved in individual recognition by humans seem to approach those needed for human language.

The hierarchical organization of many animal societies suggests possibilities for recognition that have parallels with language. The formation of a dominance hierarchy, it is important to acknowledge in the first place, might not require any individual recognition at all. Each individual can plausibly learn to recognize sets of higher- and lower-ranking opponents or even respond to one or more graded features (for instance, size, postures, or badges of dominance). On the other hand, individuals might recognize each individual opponent and respond to each in a different way. Associations with each opponent might allow inferences about the relative ranks of any two other individuals.

Especially interesting are cases in which individuals' rankings include prominent sub-groupings, and ranks across these subgroups do not follow gradations of individuals' features. In many primate groups, for instance, matrilineal groups as a whole are ranked as well as individuals within each matriline (Bergman et al. 2003). Thus a low-ranking young individual in a high-ranking matriline outranks a high-ranking older female in a low-ranking matriline. These nested hierarchies seem to arise because older relatives (mothers, aunts) shield younger ones from subordination by individuals in lower-ranking matriline. Although the pattern and the interactions are well documented, there remains the question whether this pattern is conceptualized by individual monkeys as embedded subgroups or as an overall hierarchy. Some evidence suggests that the former is possible for baboons. Playbacks of calls indicating a reversal of ranks between matriline evoke more attention than those indicating a reversal within matriline, regardless of the differences in overall rankings (Bergman et al. 2003). Baboons evidently can conceptualize a dominance hierarchy as sets of embedded individuals, although wide overlap in the ranges of responses to the two conditions raises the possibility of inconsistency in this ability.

A similar situation results from "coattail" effects in dominance hierarchies of birds (Wiley 1990; Cristal 1995). Small groups of emberizine sparrows are allowed to form dominance hierarchies in large cages in winter, when competition for food is the predominant activity. Then the top half of the hierarchy in one cage and the top half from a second cage are combined in a third neutral cage. Surprisingly, the two groups often remain coherent in the newly formed hierarchy. Each individual's rank is nested in its group's rank. The mechanism is perhaps not dissimilar to that in primate groups. The two highest-ranking individuals in a combined group interact to determine their relationship, but once this relationship is decided, the higher individual creates a coattail for its familiar subordinates. In this case, and perhaps in the primate groups also, the principal effect of the dominant individual is to let its

familiar opponents approach more closely than can others without aggression. Again the question arises: How does a relatively dominant member of a subordinate subgroup categorize opponents? First by subgroup and then by ranking within it or simply by overall rank.

Evolution of Mating Preferences by Sexual Selection

Mate choice is a well-studied example of communication. In many animals males perform conspicuous displays that increase their chances of mating. Darwin (1859, 1871) recognized that if females prefer males with certain traits, or if males with certain traits are more successful in competing with rival males, then these traits would tend to spread in a population. Even more than his theory of natural selection, this theory of sexual selection precipitated controversy among biologists. At first the primary sticking points were doubts about the cognitive abilities of females needed for preferences, but R. A. Fisher (1930) made it clear that a female's preference is no more than a neurophysiological response to a male's traits. Fisher then presented a verbal argument for accelerating evolution of male traits preferred by females. The process of sexual selection was terminated when the cost of the preferred male traits became too great.

It remained for proper mathematical analyses to verify the dynamics of this accelerating evolution (Lande 1981; Kirkpatrick 1982). Much subsequent work has confirmed predictions about mate choice in natural populations (Anderson 1994; Searcy and Yasukawa 1995). The key to the evolutionary dynamics is the genetic correlation produced when a female with a preference mates with a male with a preferred trait. Their offspring tend to inherit alleles associated with both preference and trait. The result is a genetic correlation between these alleles in the population. Within the genomes of individuals in the population, the presence of the preference allele is associated with the presence of the trait allele. This association is often called "linkage disequilibrium" by geneticists, but linkage is actually

a special case of genetic correlation, not necessarily connected with mating preferences. As generations pass, females with preferences tend to spread not only alleles for the preferred male trait but also alleles for the preference (because both males and females tend to carry both alleles). As a result of the genetic correlation of the two alleles, the preference allele spreads by "hitchhiking" with the trait allele. Another way to look at it, the preference allele spreads itself. The genetic correlation that results from preferential mating produces accelerating evolution of alleles for both of the male trait and the female preference. Sexual selection is thus a special case of natural selection, one that happens whenever individuals of one sex with a particular trait mate disproportionately with members of the other sex with the same or different trait. Preferences and other traits, to reiterate a point above, develop under the influence of alleles.

There are several points to emphasize here. First, A preference for potential mates with a particular trait is a form of communication. In the most frequent case, males produce signals to which females respond discriminately. Nevertheless, the mathematical models of sexual selection do not require direct choice of males' traits. A female might instead exert a choice indirectly. She might set conditions for mating by provoking a contest between potential mates. For instance, she might limit her matings to a particular time and place, or she might indiscriminately advertise her readiness to mate. In these cases there is no discrimination between males' traits, yet females set conditions that result in selective mating. By mating with whichever male prevails in such contests, she would indirectly choose a male whose traits allowed him to prevail against all comers. Females would, in other words, define the contest for males and then take any winner as a mate. In the case of indiscriminate advertising, a female produces a signal to which males respond by approaching. In any of these possibilities for indirect choice, genetic correlation and subsequent sexual selection would result, just as in the case of direct choice.

Second, Alleles for preferences cannot spread if females with these alleles incur net costs in terms of survival and reproduction (Pomiankowski

1987; Grafen 1990b). Responses to signals, as we saw above, must result in net advantages, on average, for receivers or their close relatives. Furthermore, sexual selection also stops when males incur net costs, when the advantages of greater possibilities for reproduction are more than offset by disadvantages for survival.

Third, Sexual selection does not spread alleles until the frequencies of the preference and trait alleles in the population exceed a threshold (or the level of genetic correlation crosses a threshold) (Lande 1981; Kirkpatrick 1982). Sexual selection does not spread mutations *ab initio*.

This hurdle applies to the initial evolution of any signal and response. No matter how advantageous communication might be, neither a response nor a signal can spread by itself. A rare mutant for a new response cannot spread without sufficiently frequent signals, and vice versa a new signal cannot spread without sufficiently frequent responses. Mutualistic signal and response must overcome a hurdle before they can spread.

Furthermore, all mutualistic interactions spread in an accelerating way once started. Responses become more advantageous as the frequency of signals increases and vice versa. It is still not clear whether R. A. Fisher (1930) had genetic correlation in mind when he proposed accelerating evolution of sexually selected traits or whether he was just thinking of the accelerating spread of any frequency-dependent mutualistic interaction (Wiley 2015). The rate of spread eventually slows down as the frequencies approach fixation, because increasing frequency of signalers results in diminishing advantages for receivers and vice versa.

Sexual selection, despite its specific application to communication during mate choice, includes parallels with the frequency-dependent evolutionary dynamics of all forms of mutualistic interaction and thus of communication in general. The evolution of mutualistic communication between individuals other than mates does not receive the extra boost from the genetical correlation that results from mating. Nevertheless it does share the initial hurdle and the subsequent acceleration that apply to all frequency-dependent mutualism.

A final point should be emphasized. The original mathematical models (Lande 1981; Kirkpatrick 1982) and subsequent derivations include the possibility that female preferences might be arbitrary. Arbitrary in this context means that mating with a preferred mate provides no benefit whatever to the female (we have already emphasized that it cannot incur a cost to the female). There are three reasons to think that such completely arbitrary preferences are unlikely to evolve. First, if alleles for two preferences exist in the same population, the one that results in a greater benefit to females spreads faster. So any preference with a benefit for females spreads to the exclusion of an arbitrary preference. Second, the same applies to the costs of male traits. Of two alleles associated with traits equally preferred by females, those with lower costs spread fastest. Finally, preferences for traits are a form of communication. Noise in communication makes the evolution of completely arbitrary signals and responses unlikely. The parameters, some ten of them, that influence the utility of a signal for a signaler (an advertising male, for instance) and the utility of a criterion of response for a receiver (a choosy female, for instance) would have to balance exactly to produce zero net utility for both signaler and receiver (Wiley 2015, 2017). Communication for mate choice, like all communication, is inescapably noisy.

Evolution of Communication in Noise

Noise requires a new approach to understanding the evolution of all forms of communication, one that is compatible in part with the preceding approaches but has advantages of defining some crucial concepts, presenting a thorough optimization of the behavior of signalers and receivers and incorporating the consequences of noise for communication. Noise opens a new perspective on the evolution of communication. Most surprising is the realization that evolution is not expected to produce noise-free communication.

Everyone is aware that noise can interfere with communication. Communication requires two parties, a signaler and a receiver. Even when

more than one signaler or receiver is active at the same time, each instance of communication is a relationship between a signaler and a receiver. A signaler produces a signal to which a receiver might respond. A signal is any pattern of energy or matter that can elicit a response from a receiver, without providing all of the power for the response. A response need not occur every time a signal is perceived, but unless a response occurs more often than at random, there is no evidence for communication.

Most previous definitions of a signal agree in stipulating that a signal must evoke a response, although it is less often emphasized that responses need to occur only more often than random. Previous definitions also require that a signal must have evolved for the purpose of communication or have a goal (or intention or function) of evoking a particular response. Often there is a complementary condition: a response must have evolved for a particular signal. These stipulations are confusing and circular: signals and responses evolve for communication which consists of signals and responses.

A signal defined as a pattern of energy that evokes a response but does not provide all the power for the response avoids this confusion. The restriction on the power of a signal excludes cases in which one individual simply overpowers another, as, for instance, in predation. A signal, on the other hand, must provide some power, enough to activate the sensory receptors of a receiver. The receiver must then provide some, often most, of the power for the response. Consequently, receivers have the final control of responses.

Signals defined in this way can originate from inanimate objects as well as living ones. Previously most definitions have excluded this possibility by insisting that signals have functions; signals without functions are instead called cues. But this measure is unnecessary. From a receiver's point of view, it makes no difference what the source of a sensation is. Signals from any source produce sensations for receivers, and receivers have final control of responses. For any receiver, including humans, information about the inanimate world has the same footing as information about the behavior of other organisms.

Nevertheless, signaling and responding by organisms can evolve. As discussed above, signals by evolving signalers are expected on average to produce net advantages in terms of survival or reproduction for signalers; responses produce such advantages for receivers. Signaling and responding by living organisms evolve jointly.

Information is another term that has caused confusion. Shannon in his pioneering papers on information theory (Shannon and Weaver 1949) described the simplest intuitive way to measure the quantity of information, but he only hinted that the quality of information ("what" rather than "how much" information) depended on the state of the signaler. A signaler's state results from its ontogeny, as described above, the accumulated influences of genes and experiences during the course of its life to present. Its state is the current condition of its body, including its nervous system and thus also its recent perceptions. The quality of information, regardless of its quantity, is the correlation between a signal and the signaler's state (Wiley 2013b). If a signal has information relevant to a receiver's survival or reproduction, alleles associated with responding appropriately to such a signal can evolve (increase or decrease in frequency in the population). If such a signal evokes a response affecting the signaler's survival or reproduction, alleles associated with producing such signals can evolve. Thus the quality as well as the quantity of information in a signal influences its evolution. Evolving signals must include some information about the signaler's state. Note once again that responses can include delayed and covert effects, such as memory or physiological changes affecting later behavior. It might include complex perceptions as well as simple reflexes.

With collateral issues resolved, a criterion for noise is possible: noise is errors by receivers. This insight by Shannon is as important as that about information. Anything that results in errors by receivers counts as noise. It can include irrelevant background energy that interferes with a receiver's detection or discrimination of signals. Background energy can include turbulence and extraneous energy impinging on the receiver's sensors. It can include signals of other species or individuals irrelevant to the receiver in question.

Noise can result from attenuation and degradation of the patterns of signals during transmission from signaler to receiver, in the atmosphere or water or even at the interface between a finger or a tongue and a receiver's skin. Noise also occurs in nervous systems. Nearly all neurons produce action potentials continuously at irregular rates, which are combined with the firing rates elicited by sensory stimulation. Little is known about how this neural noise affects perceptions of sensory sensations. Both signalers and receivers are subject to neural noise. Signalers do not always produce signals perfectly correlated with their states; receivers do not always respond appropriately to signals (Wiley 2015, 2017).

The basic insight of signal detection is that a receiver must make a decision each time it checks any of its sensory inputs (Macmillan and Creelman 1991, 2005). Because relevant signals combine with noise in a receiver's sensors, a receiver must decide whether a sensation correctly indicates the occurrence of a signal or not. Normally the combination of signal plus noise results in greater stimulation than does noise alone. Both signals and noise vary, so each produces a probability density function (PDF) of levels of excitation of a sensor. Whenever the PDF for signal plus noise and the PDF for noise alone overlap to any extent, the receiver cannot respond to appropriate signals without some error.

Another insight of signal detection is that receivers are subject to two kinds of errors, false alarms and missed detections (or errors of commission or omission or Type I and II errors in statistical comparisons). These errors result from a receiver's criterion for a decision to respond or not. The simplest criterion for response is a threshold. If the level of excitation in a sensor exceeds the threshold, then respond; otherwise, do not. More complex sensors can include filters and combinations of thresholds and filters to produce specific cognitive criteria for a response. A response, as emphasized above, can be either overt or covert, an act, a perception, or a memory. Any response might be an error.

Every time a receiver checks its input, exactly four mutually exclusive outcomes are possible. The level of excitation in its sensor might exceed

its threshold (or other criterion for response) or not; in each case, a relevant signal might have occurred or not. Excitation above threshold when a signal is present results in a *correct detection*. With no signal, only noise, the result is a *false alarm*. Excitation below threshold when only noise is present results in a *correct rejection*; with a signal present, albeit attenuated and masked with noise, the result is a *missed detection*.

A receiver in this situation can adjust its rates of error by adjusting the level of its threshold. Yet every adjustment of a threshold changes the probabilities of all four possible outcomes. For instance, by raising its threshold for a response, it would reduce its chances of a false alarm. Its chances of correct detection also decrease. On the other hand, missed detections and correct rejections increase. If a receiver lowers its threshold, its chances of a missed detection decrease, but again the probabilities of all other outcomes would also change. Most important, the two kinds of error, false alarm and missed detection, always change in contrary ways. A receiver cannot reduce one kind of error without increasing the other. Every time a receiver checks its sensors and decides to respond or not, it is in an inescapable double bind.

Signalers can influence the relationship between signals and noise for receivers. In general the more powerful or concentrated a signal, the greater its impact on the sensors of a receiver at any particular distance. Signalers thus can increase the probability of a correct detection (an appropriate response) by a receiver by increasing the exaggeration of a signal. The probability of a correct detection by an appropriate receiver in turn affects the benefit from signaling for a signaler.

The next objective is to calculate how natural selection can affect the evolution of signalers and receivers in noise. Does evolution by natural selection produce a joint solution for signaling and responding? Are there mutual advantages for signalers and receivers? Is noise eliminated by natural selection on communication? The first step is to specify net advantages and disadvantages for potential options for both receivers and signalers (Wiley 2015). For receivers, this step requires calculation of the utility of the receiver's

threshold, each time a receiver checks its sensors and decides to respond or not. This utility is a function of the signal/noise ratio (more accurately, the relationship of the PDFs for signals plus noise and for noise alone), the probability of a signal, and the level of the threshold. The threshold affects the probabilities of each of the four possible outcomes. For investigating evolution, the utility is expressed in terms of the receiver's survival $\times$ reproduction.

A similar process can specify the utility of signal exaggeration for a signaler as a function of the cost of producing a signal with a particular exaggeration and the probability of a response from an appropriate receiver. The utility of a receiver's threshold thus depends on the signal/noise ratio, which depends on the exaggeration of a signaler's signal; conversely, the utility of a signaler's exaggeration depends on the probability of a correct detection, which depends on the level of a receiver's threshold. With some calculus, it is possible to find the optimal level of a threshold for a given exaggeration of a signal or, alternatively, the optimal exaggeration of a signal for a given threshold. Further computation reveals that in most situations, thresholds and exaggeration evolve by natural selection to a joint optimum, a Nash equilibrium at which both receivers and signalers have advantages and both do as well as possible provided the other does also (Wiley 2015).

Some General Principles for the Evolution of Communication

Several important insights about communication result from these calculations. First of all, adaptation by natural selection does not escape from noise. Noise is inevitable; communication in the absence of noise is unattainable. This conclusion follows from the basic insight that both signalers and receivers face conflicting advantages and disadvantages. They also face diminishing returns: in an approach to optimal signals or thresholds, advantages increase less rapidly than disadvantages.

Second, the variables in these calculations are completely general. They apply to signalers and receivers in all cases of communication. For

instance, both exaggerations of signals and thresholds for response scale to the level of noise. Thus at close range, when background noise is minimal, optimal signals and thresholds decrease in relation to noise so that possibilities for error persist. In addition, this result applies not only to communication by nonhuman animals but also to humans and to all modes of human communication including electronic. It applies not only to communication between organisms but also to communication between and within cells. Molecular signals and receptors operate in a noisy environment, with multiple signals, multiple receptors, and chemical degradation. There is thus no reason to expect that adaptation by natural selection can eliminate noise in any form of communication. The same conclusion applies to perceptions of the external world. Optimal decisions by perceivers, based on signals from inanimate objects, cannot escape some probability of error, either false alarms or missed detections and errors of commission or omission.

Third, these calculations confirm the results of all previous calculations of the evolution of mutual interactions: neither signals nor responses can spread when both are infrequent. In the present calculations, when thresholds are too high (as when individuals have little tendency to respond to a particular stimulus) and when exaggeration of signals is too low (as when individuals have little tendency to produce them), communication collapses. Thresholds for response must not be too high, and exaggeration of signals must not be too low, for mutual communication to evolve *ab initio*.

Fourth, optimization of communication in noise opens many questions about adaptations for communication in different circumstances. Nearly every parameter in the utility functions has been measured or estimated in some case of communication (Wiley 2015), although never has there been a complete analysis of communication in noise in natural situations. There are clear predictions about the evolution of thresholds for response and for exaggeration of signals as a result of differences in signal frequency and the utilities of the four possible outcomes for receivers. A further prediction is that exaggeration of signals should not evolve in arbitrary ways but

instead specifically in ways that increase the signal/noise ratio for appropriate receivers. There is evidence that evolution of both acoustic and visual signals follows this prediction (Wiley 1991; Endler 1992; Endler and Thiéry 1996; Gomez and Théry 2004; Kemp et al. 2009). It also seems unlikely that purely arbitrary signals could ever evolve even by sexual selection. An arbitrary signal would require the multiple parameters of communication in noise to balance exactly.

Finally, although communication is never expected to reach perfection, honesty is expected to prevail. At the evolutionary optimum, both signalers and receivers benefit on average. Nevertheless, some incidence of error persists. Some errors result from random events in the environment or in signalers or receivers. Evolved adaptations by inappropriate participants also affect optimal behavior by signalers and receivers.

Deception by inappropriate signalers can reduce the utility for receivers. Eavesdropping by inappropriate receivers can reduce the utility for signalers. Communication is expected to transfer information between signaler and receiver, in other words, a corresponding perception of the actual world to their mutual advantage but always with a possibility for random errors and for manipulation by inappropriate signalers or receivers.

Investigation of communication with a hypothetical absence of errors is thus unrealistic. Noise requires study as much as signals. Nevertheless, many studies of communication, whether theoretical, observational, or experimental, take steps to reduce noise as much as possible, in order to focus on signals or responses. Study of simplified situations has its place in science, but it can also produce unrealistic results. To understand communication in any real situation, noise is as important as the signals. In other words, communication of any sort cannot be fully understood without understanding its variation in practice.

It is also clear that all communication in noise is “inferential” and “intentional.” If the “meaning” of a signal is the response it evokes in a receiver

(whether overt or covert), the meaning in the presence of noise always requires a decision by a receiver. Meaning is thus “inferential.” Furthermore, signals are often accompanied by relevant as well as noisy contexts, both of which affect the receiver’s decisions to respond or not. These decisions must often depend on the receiver’s previous interactions in a particular context and thus on the receiver’s memory of any associations with this context. They thus are “intentional.”

Signals always arrive within a context of noise. A receiver decides to respond based on its current state (including memory) and the sensations it receives. These sensations include signals (usually honest but with some noise) and relevant contexts (usually correct but with some noise). If “inferential” implies decisions by a receiver and if “intentional” implies associations for a receiver between a signal and its context, then all communication is intentional, between animals as well as humans. The decisions humans make in using language require complex criteria for responses. The distinctive features of human linguistic communication as opposed to other forms of communications lie in the specific complexities of these cognitive criteria, not in the importance of decisions or contexts in general.

Definition

A book by Robert Axelrod, published in 1984, to explain cooperative behavior in humans in light of Game Theory.

Introduction

The Evolution of Cooperation is a book by Robert Axelrod written to explain how cooperative behavior evolved and is maintained in humans in light of *Game Theory*. The book is an expansion of an earlier paper coauthored by Axelrod with William Hamilton (Axelrod and Hamilton 1981). The purpose of the research was to build on a theory of what conditions are necessary for cooperation to emerge, specifically in a scenario in which individuals can pursue their self-interest without a central source of authority (i.e., societal rules or laws) to force cooperation through future consequences.

Adaptive Cooperation

Drawing on Game Theory and using computer simulations, Axelrod investigated the power of different strategies in a sequential (i.e., multiple rounds) paradigm of the prisoner's dilemma. Axelrod invited scholars in Game Theory to submit possible strategies, and each was tested

against other strategies in a computer simulation. Through this work, the “tit-for-tat” strategy emerged as the most successful, shedding light on the nature and origins of human cooperation. The tit-for-tat strategy is where the player cooperates in the first round and then mimics the choice of the other player’s previous round in all subsequent rounds.

The prisoner’s dilemma game involves a simultaneous choice (i.e., each player must make the choice without knowing what the other will do) between two players to either cooperate or defect. In this game, defection yields a higher payoff than cooperation when paired with a cooperate choice from the other party, but if both defect, they both do worse than if both had cooperated. In addition, the cost of being defected on after cooperating is still greater (see ► [“Prisoner’s Dilemma”](#) entry for more detail).

Analysis of the data from the simulations identified four properties which accounted for the success of the tit-for-tat strategy: (1) the potential for harmony by avoiding unnecessary conflict by cooperating as long as the other player cooperates, (2) provocability in the form of retaliation for a defection by the other by defecting in the next round, (3) forgiveness after responding to a provocation with a defection by responding to instances of cooperation with cooperation after this, and (4) clarity of behavior so that the other player can adapt to the tit-for-tat strategy pattern of action.

In a single encounter, the most effective choice is to defect as this will yield the highest payoff: If the individual believes, or expects, that the other is going to cooperate, then they will gain the most points by defecting. Moreover, even if the individual believes the other will defect, it is still preferable to defect as the cost for cooperating and being defected on is greater than mutual defection. Therefore, no matter what the other player does, it is more strategic to defect. However, in a pool of other consistent defectors, this would yield the second most costly solution (with the first most costly being cooperating with a defector): The other player is naturally in the same situation, meaning, in a single encounter, both should defect, but if so the players will do

worse than if both had cooperated, leading Axelrod to conclude that individual rationality leads to a worse outcome for both than is possible (Axelrod 1984). Thus, the evolution of cooperation required that individuals have a reasonably large chance to meet again so that they have a stake in future interactions rather than just the interaction in hand. Under the conditions of potential repeat encounters, an initial disposition to cooperate (followed by reciprocation) can indeed emerge as adaptive in a world of self-interested organisms without any central authority.

From his simulations, Axelrod proves that cooperation can evolve against three potential problems. Firstly, Axelrod shows that cooperation can arise even starting from a in a world of unconditional defection. That is, cooperation can evolve from small clusters of individuals who qualify their initial predisposition to cooperation on reciprocity. Secondly, a strategy based on reciprocity can continue to thrive in a world where various other different strategies are also being attempted as it will prove superior to these alternatives in the long run. This is again due to the protection provided by retaliatory reciprocation of defection as well as the ability to recover from a vicious cycle of defection via forgiveness. Finally, once a collectively stable system is established on the basis of reciprocity, cooperation will protect itself from invasion by less cooperative strategies by outcompeting them in the long run. The only other strategy that is also collectively stable is to always defect. This strategy can never be invaded as long as alternate strategists arise one at a time. However, if tit-for-tat strategists arise as a cluster, it will thrive better and become dominant over time. That is, assuming individuals have some control as to who they interact with, a cluster of tit-for-tat strategists will interact within itself with increasing probability rather than with the always defect strategists, retaliating when they do to prevent these strategists from any further gain after the first case of defection.

Axelrod illustrates the evolution of cooperation using the real-world example of a prisoner’s dilemma: soldiers in World War I. When these soldiers were not engaged in combat, they spent most of their time in trenches near each other

without attempting to harm each other. As a volley of grenades could easily be answered with a retaliatory volley of grenades and mutual survival was more in everyone's interest than mutual destruction, cooperation (at least insofar as refraining from killing each other outside of direct battles) was maintained via tit for tat.

The Evolution of Cooperation goes further than merely providing an overview of how cooperation arose and is maintained by applying this knowledge to provide advice for individuals faced with a prisoner's dilemma style situation and suggests how to promote cooperation. When faced with circumstances demanding the selection of either cooperative or competitive strategies, outcome can be optimized by following four rules: (1) Do not be envious as envy is self-destructive. That is, rectifying a discrepancy between your own success and another's can only be achieved with defection, but defection leads to more defection and mutual punishment in an environment of reciprocity. (2) Do not be the first to defect as, in a system of reciprocity, this will likewise lead to a cascade of mutual punishment. (3) Reciprocate both cooperation and defection as a strategy of consistent defection is only suppressed by punishment via reciprocated retaliatory future defection. (4) Do not attempt to be too clever by mixing up the strategy as, assuming that the game is likely to continue for at least one more interaction, reciprocation will never allow defection to go unpunished. Building on this, when it comes to promoting cooperation, Axelrod suggests emphasizing the future ("enlarging the shadow of the future," 1984, p. 129) as mutual cooperation is only stable if the future is sufficiently important relative to the present, changing the payoffs making the long-term incentive for mutual cooperation greater than the short-term incentive for defection, teaching people to care about each other, and making the concept of reciprocity clear.

Conclusion

The Evolution of Cooperation is a book by Robert Axelrod, published in 1984, to explain cooperative behavior in humans in light of Game Theory, specifically, multiple rounds of the prisoner's dilemma

game. The "tit-for-tat" strategy (where the player cooperates in the first round and then mimics the choice of the other player's previous round in all subsequent rounds) emerged as the most successful, shedding light on the nature and origins of human cooperation. Axelrod proves that such cooperation can evolve against several potential problems and outcompete alternate strategies.

[Criminal acts and criminal behavior](#)

Definition

Crime consists of acts which contravene the human moral code and statutory law. Evolutionary principles such as conflict and kin selection, reciprocation, sexual selection, parental investment theory, and strategies to outcompete rivals are used to explain the evolution of crime and criminality.

Introduction

The application of evolutionary principles to our understanding of crime and criminality is a recent development due to the advent of evolutionary forensic psychology. To understand the functionality of crime using an evolutionary perspective, it is important to define what crime and criminality are. A diversity of social definitions has been developed by social scientists; for our purposes here, however, we will resort to a legal approach. Despite there being cross-cultural discrepancies in how minor crimes are perceived and defined, McGuire (2004) has highlighted remarkable uniformity in how serious crimes are considered cross-culturally irrespective of the criminal justice systems employed. It is worth noting that where behavioral responses are observed to be universal, it can be taken as suggestive that they arise from ancient common origins (Brown 1991). Hence, homicide, rape, pedophilia, incest, aggravated burglary, and arson are examples of offenses that, cross-culturally, are considered as *mala in se* crimes – a legal term used to describe criminal behaviors which contravene the human moral code (Davis 2006; Taylor 2016). These types of crime are considered as very serious and induce a sense of universal repugnance.

Another cross-culturally recognized legal concept is corpus delicti. Corpus delicti encapsulates the idea of “body of crime.” Put simply, this refers to evidence and information proving that a criminal event has occurred. To ascertain corpus delicti, there has to have been a guilty act committed such as homicide (*actus reus*) and the presence of a guilty mind such as harming with intent (*mens rea*). To establish a suspect’s guilt of a specified offence, both *actus reus* and *mens rea*

are considered, and evidence is presented in a court of law. If the crime committed is of a less serious nature such as breaking the speed limit, then the perpetrator is convicted under statutory law which varies cross-culturally. This variation is socially determined, and the punishment for breaking such regulatory statutes prohibiting specified behaviors is presided using set tariffs (these are defined in *mala prohibita*). Due to their cross-cultural commonalities (and, in particular, how these criminal acts elicit very similar legal and social responses cross-culturally), evolutionary principles can best be used to explain *mala in se* crimes. Evolutionists consider that such crimes can be thought of as based around decision-making that arose to resolve recurrent ancestral challenges. In contrast, due to their cross-cultural variation, this is unlikely to be the case for *mala prohibita* crimes. Hence, here we explore adaptationist explanations that have been developed in order to understand the relationship between evolutionary principles and *mala in se* crimes. The first evolutionary explanation considered is “conflict related to status and mating opportunities.”

Conflict Related to Status and Mating Opportunities

Duntley and Shackelford (2008) reviewed the implications of interindividual conflict over status, material, and mating resources. Their basic contention is that increases in status would require an individual to develop specialized cognitive adaptations brought about by selection pressures as a means of ascending the hierarchy. Having resources such as food, territory, tools, and weapons implies an individual’s (usually male) competency and capability to survive and protect any mate and offspring from situations of jeopardy. During the ancient past, ascending the hierarchy would most likely have increased inclusive fitness. Conflict can occur both across (inter) and between (intra) the sexes. In the case of intra-sex conflict, males are more likely to take risks in order to secure mating opportunities. It is no surprise therefore that, from an evolutionary perspective, men who used violence as a risky strategy

were, in many cases, more likely to achieve their ambition of securing mating opportunities through the intimidation of their male competitors. The use of violence therefore, as argued by Daly and Wilson (1988), can be an adaptive strategy to ward off potential male competition vying for mates and resources.

Given the importance of status, material, and mate resources, males can resort to strategies of cheating, such as theft; achieving reproductive success without consent, such as rape; and attaining status and material resources through the use of violence and homicide. Theft is an antisocial behavior that deprives an individual (the victim) of their status and resources. This can potentially increase the perpetrator's social profile through having stolen status and resources ultimately used in an effort to attract a mate. Rape is a *mala in se* act because it is a sexual behavior forced upon a non-consenting female (most frequently). This is costly to the female both emotionally and physically, and additionally, she could be carrying offspring from a man who has bypassed female mate choice criteria. From the male's perspective, however, he has increased the chances of passing on his genes which might not have happened had he been subjected to female mate choice criteria.

The use of violence can also signal an individual's status as being non-exploitable and act as a buffer against violent confrontations in the future. This can also enable such an individual to obtain assets from less resilient competitors. In the case of homicide, cost-inflicting competitors are permanently removed and their resources assimilated. Buss (2005) explains violence and homicide using an evolutionary perspective. Winners of confrontations gain the reputation of being tough and can avoid having to consolidate this status through future fights. Losers of confrontations may concede their resources to the winner and gain the reputation of being exploitable. They may also become more likely to endure future fights because of their status as exploitable.

Ultimate explanations help us to understand why males were more likely to turn to violence than females in our hominin ancestry. In most present-day societies, however, levels of violent

aggression are perceived as substantially lower than during our ancestral past (Pinker 2011). This begs the questions of why this should be the case and how did it arise. Most individuals conform to the social values set within their society and develop a moral compass courtesy of a socialization process which reflects these values. Moreover behaviors considered to be appropriate are often underpinned by morals condoned by society. Antisocial behavior such as criminal acts contravenes these values. Moral behavior can be considered to be a hominin legacy which served a function in our evolutionary past. Our next evolutionary explanation relates to the importance of how morality evolved to promote prosocial behavior.

Evolution of Morality in Relation to Criminal Behavior

Social scientists generally consider that a sense of morality arises out of cultural practices. Evolutionist Denis Krebs begs to differ. Krebs (1998) considers there are three important pathways which direct the evolution of morality in all cultures: altruism via reciprocity, deference to authority, and devotion. In order to understand the importance of altruism, it is important to consider how early hominins lived and survived in a challenging environment. Fossil and artifact records suggest that ancestral groups consisted of between 20 and 200 individuals, many of whom were genetically related and others considered as fictive kin. According to Barkow (1989) cooperation between these hominin dwellers was key to their survival and relied on close bonds and reciprocation. Trivers (1972) previously referred to this as reciprocal altruism and deemed it necessary for the creation of a prosocial living environment. Under these living conditions, all individuals benefited from the results of successful foraging and hunting regardless of whether they were the ones responsible for the successful expedition. This implies that in order to survive and reproduce, all members must play by the rules of cooperation and sharing. Those who do not but still try to reap the rewards are likely to have been

considered as free riders and once detected had either to conform to the group norms or risk being ostracized. Trivers also claimed that living under these conditions helped to create emotional ties and provided selective forces for the evolution of a moral code.

Empathy and morality are important facets in the development of prosocial behavior. In a society where laws have been developed, consensus behavior becomes prosocial rather than antisocial. Nevertheless, free riders in present-day societies according to Mealey (2005) and Workman and Reader (2014) are likely to be retained in the population provided their numbers are proportionately low. Hence, cooperative societies open up opportunities for free riders. Nayef Al-Rodhan (2008) states that we act according to our emotional self-interest directed by “genetically coded survival instincts. . . .modified by the totality of our environment and expressed as neurochemically-mediated emotions and actions” (p. 16). We therefore rely on laws and rules to provide an environment of organized social order. A moral code, on balance, according to Ruse and Wilson (1985), helps increase our inclusive fitness. They draw upon the concept of epigenetic rules that are driven by our genes. Why this is important in the evolution of crime rests on how some of our laws have developed over time. One such example is the illegality of incest and why the tariff of punishment is high across many societies. Incest is a *mala in se* crime. In the case of incestuous relationships, the consequences will be an increased probability of having a karyotype littered with deleterious double recessive genes (technically known as “inbreeding depression”). According to Ruse and Wilson, these moral codes are grounded in our genotype and increase the likelihood of offspring survival. Hence, developing a law against incest is there for good reason, and such behavior is frequently punished by criminal justice systems. This is a good example of evolution and cultural development (i.e., laws) working in tandem.

With regard to the second facet of Krebs’ pathway, deference to authority, it can be seen that individuals who obey the law and behave prosocially rather than antisocially are more likely to survive. Krebs argued that a social hierarchy existed among early hominins dictated by “alpha

males.” Those who refused to show deference to such males either engaged in defiance through fighting them and winning a new founded status or fighting and losing sometimes resulting in death. This rarely happens in modern society as humans show deference to the societal infrastructure (e.g., the police force) and legal system. In the case of devotion, Krebs’ third pathway, the development of strong attachment bonds, is the glue which keeps relationships intact. It is this which helps promote the survival of any offspring. Krebs’ model is very informative in understanding the point of origin for many *mala in se* crimes. This can be seen in parental rejection and neglect of offspring, which warrants a high legal sanction. Equally, when an individual contravenes codes of appropriate behavior such as taking another person’s rights using violence or rape, then there are high legal tariffs to be served.

In addition to common cross-cultural patterns, at the individual level, scanning technology provides empirical support for an evolved neural basis of moral behavior. In some studies evolutionary psychologists have explored activity in the brain using fMRI scans while the participant is subjected to moral-oriented information. The data from studies adopting this approach reveal the existence of evolved brain mechanisms enabling us to make moral-based decisions. According to Taylor and Workman (2020), “This. . . .provides impetus to the notion of there being moral universals, which, when transgressed, can be considered to be universal crimes.” Research by Greene et al. (2001) provided evidence using fMRI scans of specific activation of localized areas in the brain when making moral decisions. Such specific areas include the medial frontal gyrus, posterior cingulate gyrus, and angular gyrus, all of which are particularly activated during moral-personal decision-making. Having evolved a neural substrate to help avoid seriously harming others (largely kin and kith) in the group would have been an effective adaptation (Taylor and Workman 2020). It is likely that the evolution of empathy allowed us to inhibit *mala in se* acts. For some individuals, however, empathy is reduced or absent. Interestingly, for many of these individuals, a diagnosis of a personality disorder helps us

understand why they are attracted to what is considered a criminal lifestyle. In recent years psychologists have identified a cluster of specific personality factors labeled the “dark triad” that increase the likelihood of criminality developing.

Crime and the “Dark Triad”

In 2002, Paulhus and Williams introduced the concept of the “dark triad.” They describe three sub-clinical personality traits: narcissism (callous and self-interest), Machiavellianism (manipulative exploitative), and psychopathy (emotionless, cold, impulsive, and risk-taking). The “dark triad” is a collection of traits clustered in individuals who have a tendency for committing crime (often *mala in se* crime). Whereas traditional psychological approaches question why the “dark triad” is maintained in the population, evolutionary psychologists believe they may have the answer. According to Jonason et al. (2009), the “dark triad” traits promote success in short-term mating and are correlated with increased intra-sexual competition. In 2017 Međedović, Petrović, Želeskov-Đorić, and Savić investigated the association between psychopathy and reproductive success by studying a Serbian male prison population. They found that some traits typifying the psychopath’s lifestyle (for instance, irresponsible and impulsive) actually correlated with fewer offspring but other (interpersonal) traits such as manipulation and dishonesty were related to having more surviving offspring. It appears that manipulation and dishonesty facilitate the psychopath’s ability to cheat (Lyons 2015). Međedović et al. conclude that different facets of psychopathy influence the number of offspring fathered. It is not only males, however, who can receive the diagnosis of the “dark triad.” Brewer et al. (2019) subjected female online participants to a series of questionnaires that measured levels of narcissism, Machiavellianism, and psychopathy. They found that high scorers on the “dark triad” engaged in sexual deception. In particular narcissism was associated with blatant lying, Machiavellianism with blatant lying and lying to escape confrontation, and psychopathy with self-serving deception and an increased

likelihood of exhibiting an avoidant relationship attachment. This latter point may be a consequence of having a callous unemotional and non-empathic disposition with a tendency for risky behavior. Over all it appears that, under certain circumstances, criminals who have the “dark triad” may be using an alternative strategy to boost their inclusive fitness.

This hypothesis is supported by McGuire and Troisi (1998) who claim that the ability to deceive and exploit others can be adaptive. Mealey (2005) adds that this adaptive strategy is more likely to be maintained among populations where reciprocity is prevalent. McGuire and Troisi state that, “In a society made up primarily of reciprocators, genes for cheaters can enter the population and remain, provided persons with such genes reproduce” (1998, p. 191).

A well-publicized account of criminal behavior by a man who clearly exhibited the “dark triad” is Mick Philpott. In 2013, UK citizen Philpott was accused of murdering his six children by deliberately starting a fire to the home using petrol while his children slept. Both he and his wife were seen on television crying and appealing to the public to provide the police with any information that could lead to the arsonist’s arrest. It was a pretense that was maintained during and post investigation. When his lifestyle choices and previous behavior were considered, it became apparent that he was a dangerous criminal psychopath. He had 17 children with different women and used violence to control the family. He had previous convictions of assault for which he was imprisoned. He later confessed to staging the fire so that he could then save the children and be seen as the hero. This typifies the egotistic grandeur of a man who has the “dark triad.”

The presence of the “dark triad” goes a long way toward explaining many *mala in se* crimes. Most serious crime, however, is committed by individuals who have not been diagnosed with a personality disorder. The majority of these serious criminals are males (Archer 2004; Campbell 1999; van Vugt 2009). But why should this be the case? Can this difference be accounted for using explanations from an evolutionary perspective? Evolutionary psychologists explain this difference

by drawing on sexual selection theory and the concept of asymmetrical parental investment.

Sexual Selection and Asymmetrical Parental Investment in Relation to Male Violence

Taylor and Workman (2020) draw upon sexual selection and parental investment theories as explanations for why more risky behavior such as aggressive and violent acts is performed by males than females. Females invest more heavily in the production of offspring than males throughout development and in particular through the processes of gestation, parturition, and lactation. It therefore makes sense for them to be more risk averse and to avoid physical aggression (Campbell 1999; Kanazawa 2009). In contrast, when males engage in aggressive acts, it is less likely to be damaging to their offspring. Archer (2004) and van Vugt (2009) argue that aggressive behavior might have provided male hominins with fitness benefits such as status, reputation, and resource gain. van Vugt labeled this the “male warrior hypothesis.” Support for the “male warrior hypothesis” comes from a study by Bourgeois and Fisher (2018) which showed an increased likelihood of males committing violent robbery than females and that a victim was more likely to incur injury when more than one male perpetrated the offence.

If we had to predict who is most likely to commit a violent crime then, rather than focusing on males in general, we should focus on young men. In fact the statistics show a preponderance of younger males committing violent crimes when compared with their older counterparts. According to Kanazawa (2009), adolescence is a period in a male’s life where he strives for status and resource attainment as an evolved strategy of attracting females. Kanazawa suggests there is a robust link between sexual selection and criminal violence among young males. Beyond the age of 30, male violence decreases as they are more likely to have reproduced and the costs of violent behavior outweigh the benefits of providing

parental care (Cartwright 2016; Kanazawa and Still 2000). There are exceptions. As we have seen, some males (such as Philpott discussed earlier) often fail to shift from aggressive behavior to a parental caring mode. The murder of children is a cross-cultural phenomenon that is a heinous crime classified under *mala in se*. Can evolutionary principles be applied to infanticide?

Infanticide: The Cinderella Syndrome

Related to the above, one of the contentions of parental investment theory is that the closer the kin, the greater the probability that parents will invest their time, effort, and resources in them. Parents will invest in their direct offspring first and then to genetically related extended family members. Conflict does arise between kin but far less frequently than observed in nonkin. Parental investment theory can help to explain this difference in conflict response through the fact that kin share genes by common descent, leading to a reduction in physical aggressive response. In a typical family of genetically related individuals, Daly and Wilson (1988) argue that the level of conflict is reduced and more likely to be replaced by altruistic behavior. In contrast, there is a preponderance of conflict in families which consist of unrelated individuals, especially when we consider homicide rates across stepparent and stepchild relationships.

Dustin and Alcock (2018) claim that, in collectivistic societies, kin often adopt the children of their genetically related extended family in situations of loss. In individualistic societies, however, reconstituted families (i.e., stepparents and stepchildren) in which there is no sharing of genes by common descent, stepchildren are often treated less favorably. This scenario is well recognized in individualistic societies. In line with the fairy-tale character Cinderella, who is treated harshly by her stepmother, this phenomenon has been labeled the “Cinderella syndrome.” Given that the offspring’s contribution to the stepparents’ inclusive fitness is generally zero, from an evolutionary perspective, we can predict the level

of parental investment will be lower for stepchildren than for biological offspring. In extreme cases this can lead to *mala in se* crimes. Daly and Wilson (1988), for example, found that infanticide was 120 times greater in a family where one stepparent was living. They also found that the probability of a 2-year-old child or younger experiencing physical abuse is seven times more likely if one of the parents was the child's stepparent than when both were biologically related (Daly and Wilson 2007). This finding was supported by Archer (2013) who uncovered evidence that in nine out of ten studies of child infanticide, the frequency and intensity of violence perpetrated by the stepparent significantly exceeded that committed by biological parents. His findings support the "Cinderella syndrome" which accounts for why some stepparents fail to cope within a reconstituted family context.

Conclusion

While social scientists and mainstream psychologists explain the existence of crime in terms of proximate situational variables, evolutionary psychologists suggest the emergence of criminal behavior can be explained by adopting adaptationist thinking. Crimes which are considered universally to be serious (*mala in se* crimes) can be seen as ways of solving ancient recurrent challenges. A number of explanations are presented for such crimes based on evolutionary principles. Such explanations include consideration of kin selection, sexual selection, parental investment theory, the maintenance of the "dark triad," and the "Cinderella syndrome." Some evolutionists consider that, by relating current criminal practices to evolved propensities, we may be better able to develop an overarching explanation for such serious antisocial behavior.

Evolution of Desire, The

David M. Buss

Department of Psychology, University of Texas at Austin, Austin, TX, USA

Synonyms

Attraction; Mate preferences; Mate retention; Mate selection; Mating; Mating psychology; Mating strategies

Definition

This book provides a unified theory of human mating strategies, anchored in the best scientific evidence available on sexual psychology.

Introduction

The Evolution of Desire: Strategies of Human Mating was first published by Basic Books (Buss 1994). It took 4 years to write and represented a synthesis of a decade of research on the psychology of human mating by the author. Two chapters were added to a revised edition in 2003, although the original ten chapters remained in unmodified form. *Desire* was updated and revised thoroughly from top to bottom (Buss 2016) and represented an explosion of empirical research in the years since its original publication. *Desire* has become a citation classic (more than 2,000 scholarly citations as of 2016). It is widely used in college courses. It is used by scientists to guide mating research. And it is used by everyday readers to inform their own mating lives.

Although one previous excellent book had been written about the evolution of human sexuality – Donald Symons’s (1979) classic treatise, *The Evolution of Human Sexuality* – the goals of *The Evolution of Desire* were broader than sexuality per se. It aimed to look at human evolved

Evolution of Culture

► Human Nature and Biocultural Evolution

psychology of mating more expansively, including all the action that happens prior to, and after, sexual activity proper – strategies of mate competition, mate attraction, mate selection, mate retention, mate poaching, conflict between the sexes, mate ejection, and remating over the life span.

A key theoretical premise of *The Evolution of Desire* is that humans have a menu of mating strategies, not just a single one, and that some of these strategies show important gender differences. Humans most obviously have long-term mating (sometimes called pair-bonding, committed mating, or marriage), although this turns out to be rare among mammalian species, characterizing perhaps only 3 %. Humans also have short-term mating or casual sex, serial mating, mate poaching, and infidelity, which represents a mixed mating strategy of one long-term mateship with some sex on the side. Understanding all mating strategies requires first identifying what women and men want. It all starts with desires in a mate.

Desires in Human Mating

What people desire in a mate, selective mate preferences, captures a key component of Darwin's theory of sexual selection. Desires draw us to some potential mates. They repel us from others. Iterated over generations, the desires of one sex determine the qualities favored or shunned, producing evolution or change over time. Prior to 1989, little was known about what women and men wanted in long-term mates. David Buss's 37 culture study, involving 10,047 individuals on five continents and six islands, provided the first massive cross-cultural findings on this key topic (Buss 1989a).

The Evolution of Desire synthesized this and all scientific studies available at the time in Chapter 2 (What Women Want), Chapter 3 (What Men Want), and Chapter 4 (Casual Sex). These chapters describe sexual similarities in mate preferences, universal sex differences, and cultural variation. Universal preferences include the desire for mates who are kind, understanding, intelligent, dependable, emotionally stable, and healthy. Importantly, people worldwide want

mates with whom they are in love and who are in love with them, overturning conventional social science beliefs that love was a Western European invention and not a universal across cultures. The emotion of love exists worldwide, appears in long-term but not short-term mating, and serves as a form of psychological commitment – an idea articulated independently by the economist Robert Frank (1988) and David Buss (1988) the same year.

Desire also described universal sex differences. Women more than men desire mates who provide good economic resources, as well as the attributes linked with long-term resource acquisition such as ambition, industriousness, and social status. Men more than women prioritize physical attractiveness and relative youth – important cues to fertility. These are universal sex differences that were predicted in advance by evolutionary hypotheses; they have been robustly replicated by dozens of researchers since *Desire*; and they show no signs of diminution over time. Cultures also differed dramatically in some desires, such as the desire for virginity in a potential spouse. Swedes, for example, did not value virginity at all, whereas Chinese at the time saw virginity as virtually indispensable (Buss 1989a).

Chapter 4 delves into the deep scientific evidence for sex differences in the psychology of short-term mating (as contrasted with long-term mating). David Schmitt and David Buss were the first to systematically document gender differences in mate preferences as a function of this temporal context (Buss and Schmitt 1993). Men, for example, prioritized high sex drive, sexual experience, and physical attractiveness in short-term mating, while despising prudishness and a low sex drive. Women also increased the importance they attach to physical appearance, but ramp up their desire for immediate resource displays from a man. Chapter 4 also delves into the scientific evidence for gender differences in the desire for sexual variety. It highlights its many psychological design features of short-term mating psychology, including attraction to novel partners, letting little time elapse before seeking sex, relaxing standards for a partner, and showing a sexual over-perception bias that causes men to

over-infer women's sexual interest. It also speculated about men's attraction decrement post-intercourse – designed to motivate a hasty post-copulatory departure and minimize investment and commitment – a hypothesis that was subsequently tested and supported only for men pursuing a short-term mating strategy, as predicted (Haselton and Buss 2001).

Mate Competition: Attraction and Derogation

Several chapters in *Desire* capture what is known about intrasexual mate competition – the second key component of Darwin's theory of sexual selection. They focus on two generic strategies – *tactics of attraction* and *derogation of competitors*. According to sexual selection theory, these should focus on dimensions desired by the other sex. Stated differently, the desires of one sex establish the ground rules of same-sex mate competition. Studies bear out this key prediction. Both men and women display and deploy tactics that involve acts of kindness, intelligence, and brimming good health. Sex-differentiated tactics involve resource display, physical protection, and appearance enhancement. Women, for example, spend more than nine times as much money on beauty products. Men display status, ambition, and resources and show a willingness to commit them to one woman, at least in long-term mating.

Tactics for attracting short-term mates differ somewhat. Schmitt and Buss (1996) found that men seeking short-term mates were more likely to engage in immediate resource display, whereas women were more likely to give off cues to immediate sexual access. Because more men than women seek short-term mates, women generally have their pick on the short-term mating market, and these sexual signals are extremely effective for them. Men sometimes deceive women, feigning long-term interest for the purpose of gaining short-term sex. *Desire* goes into depth about these and other tactics of short-term and long-term mate attraction.

Derogation of competitors – the ways in which we use language to impugn the character and

desirability of our rivals – is a second strategy in the arsenal of human mate competition. And the desires of one sex again set the ground rules of the game. Men are more likely than women to impugn a rival's status, resources, and athletic prowess. Women are more likely than men to derogate their rival's physical attractiveness (e.g., “she has heavy thighs”) and sexual selectivity (e.g., “she slept with the whole football team”). Men seeking a long-term mate are hugely turned off by a woman's promiscuity, since it jeopardizes his paternity certainty. They are not averse to this quality when seeking a short-term mate. As the actress Mae West once noted, “Men like a woman with a past because they hope history will repeat itself.”

Conflict Between the Sexes

One chapter of *Desire* that garners much attention centers on sexual conflict – the ways in which men and women interfere with each other's mating strategies. Conflict between the sexes occurs on the mating market. One example stems from differing perceptions of mate value, such as when a man approaches an attractive woman he believes is within his mate value range, but she does not concur. Another source of conflict is when one person is seeking a long-term mate and the other a short-term mate, which has selected for strategies of deception. A man might feign long-term interest for short-term sexual access. A woman might present herself as costless sex and then attempt to convert the relationship into one of long-term commitment. These are all forms of “strategic interference,” whereby a member of one gender blocks or impedes a strategy pursued by the other (Buss 1989b).

Committed couples sometimes break up. The causes are well predicted by sexual strategies theory and a deep understanding of human mate preferences. Men's failure in resource provisioning, for example, violates what women want. Women's decrement in appearance or older age sometimes causes men break up. Conflict over pooled resources and over in-laws are common sources of friction. And infidelity, sexual or financial, violates desires and often leads to breakups.

Mate Retention and Mate Ejection

Tactics of mate retention and mate ejection also should follow the logic of evolved desires. Successful tactics of mate retention embody what a mate wants, such as kindness, attentiveness, love, affection, gifts, resource flow, and sexual access. *Desire* describes how men's efforts at mate retention are partly a function of women's youth and attractiveness (Buss and Shackelford 1997). Women allocate more effort to retaining mates who are higher in status and income.

Successful tactics of mate ejection are typically those that violate men's and women's initial desires. Being cruel violates the desire for kindness. Having an affair violates the desire for sexual loyalty. Withdrawing resources violates the desire for provisioning.

Mating Over the Life Span

Nothing remains static over time. Humans undergo some predictable changes, but also show enormous variation in those changes. Fertility, for example, inexorably declines with age for both sexes. Importantly, women and men show different life span fertility curves, with women showing an earlier and steeper decline than men. Access to status and resources is considerably more variable. Male status and resources rise through the 20s and 30s, along with hunting skills in traditional societies and job promotions in modern societies. Nonetheless, some experience dramatic declines with age, and others experience dramatic rises with age. In short, status and resources over the life span peak later than does fertility and show much greater variability over the life span than does fertility. These life span conditions influence important dimensions of mating – whether couples stay together or divorce – individual mate values upon reentry into the mating market and many others.

Condition-Dependent Mating Adaptations

Throughout the book, *Desire* emphasizes that human mating adaptations are contingent on key

contexts. Personal mate value, for example, is a context that affects one's ability to implement a preferred mating strategy. Sex ratio in the mating pool – the number of men relative to the number of women – influences both mate value (the rarer sex has higher on-average mate value) and also whether mating strategies shift more to short-term mating (e.g., for men, when there is a surplus of women) or long-term mating (for men, when there is a surplus of men). Our mating psychology is also contingent on many other circumstances: parasite prevalence in the local culture or ecology, the degree to which parents and kin influence and constrain an individual's mating decisions, women's access to resources, level of gender equality, and many others.

Conclusion

In 1994, *The Evolution of Desire* crystallized a new field – strategies of human mating. In the decades since its original publication, this field has mushroomed. Thousands of scientific articles have been published on the topic since 1994, and the 2016 revised and updated edition of *Desire* highlights some of the most important scientific developments. We now know the broad outlines of the strategies of human mating. But new work continues to reveal facets of our mating psychology previously undiscovered. In this sense, the scientific understanding of human mating strategies keeps expanding and deepening. Given the centrality of reproduction to evolution by selection, and of mating to reproduction, it should perhaps not be surprising that human mating psychology shows this enormous complexity of design. There still remains much mating gold to be discovered by intrepid scientific explorers.

Synonyms

Evolution of social emotions; Social emotion evolution

Definition

Human emotion evolved – that is, came to be via natural selection – in an inherently social context; human emotions are therefore not separable from their social nature.

Introduction

While it is widely recognized that there is an important interplay between emotions and human social life, the social mechanisms by which emotions came to be via natural selection are not often considered. Extant theorizing on the evolution of emotions (hereafter referred to as *EvoEmo*) has traditionally focused on the modular cognitive or neural architecture that produces a small set of emotions, which are believed to serve discrete functions in the service of reproductive fitness (Cosmides and Tooby 2000; Tooby and Cosmides 2008). In these modular views, social functions are either not addressed or are just one type of function that may be important for reproductive success. Importantly, however, such modular theories are not the only perspectives that focus on the functions of emotions, nor the only theories that speak to how emotions evolved.

Two theoretical perspectives on emotion – those that adopt functionalist frameworks and those that adopt constructivist frameworks – offer important insights into *EvoEmo* that differ from classic evolutionary perspectives. Functionalist perspectives on emotion investigate a range of functions of many different emotions in modern humans and, in particular, often focus on the social functions of emotions and the social contexts in which emotions arise. Functionalist views sometimes, but not always, explicitly draw on evolutionary logic. Constructivist views of emotion, which postulate that emotions emerge from a set of more basic or fundamental ingredients rather than from modules, offer an alternative theoretical starting place for understanding *EvoEmo*. This entry presents the argument that synergy between functionalist and constructivist views provides insights into how and why

emotions evolved in social contexts and evolved to serve social functions.

The Evolution of Emotions and the Importance of Functions

The empirical study of EvoEmo is particularly challenging because emotions, like other psychological phenomena, did not leave a fossil record. Further, unlike the case of other behavioral phenomena, it is challenging, if not impossible, to make strong inferences about emotions from what is left in the fossil records. In contrast to the study of EvoEmo, for example, it is possible to study the evolution of hands by examining fossils (e.g., Almécija et al. 2015; Domínguez-Rodrigo et al. 2015). Variation observed in fossils enables theorizing about how grasping, and complex behaviors that require grasping such as throwing, clubbing, and tool making, came to be over evolutionary time via natural selection (e.g., Marzke 2013; Young 2003). No such option for linking the fossil record to emotions exists, either directly or via logical inference. As a result, scientists with interests in EvoEmo have largely focused on the study of modern humans.

In the absence of fossil record, emotion theorists interested in EvoEmo have turned to several sources of data from modern humans to support their claims. For example, classic EvoEmo theories stipulate that a small set of emotions came to be during the early period in which humans appeared – typically during the Pleistocene epoch – because they met unique evolutionary demands for reproductive fitness (Cosmides and Tooby 2000; Tooby and Cosmides 2008). This set of assumptions confers the idea that emotions are biologically hardwired and therefore present at birth in humans and universal (i.e., all humans have them). As a result, developmental data are thought to be one source of support for claims about the modular and hardwired nature of emotions, grounded in the logic that if human infants demonstrate evidence for this small set of emotions, then those emotions must be biologically endowed (for recent empirical example of infant

studies on discrete emotion perception: Cong et al. 2018; Lee et al. 2015).

Cross-cultural data are also levied to support EvoEmo claims. If a small number of emotions are perceived and expressed in all human cultures, then this is held as evidence for the idea that the small set of emotions is evolutionarily conserved because it is universal in all people (for recent examples: Cordaro et al. 2018; Fang et al. 2018; Sauter et al. 2010, 2015). Data of these sorts have been challenged robustly in recent times, calling into question the methods used, interpretation of the data, and whether the theoretical claims made based on those data are valid (a review of those challenges is far beyond the scope of this entry, but see Barrett et al. 2018; Gendron et al. 2015; Nelson and Russell 2013; Widen 2013).

Another source of data that may speak to EvoEmo is data on the function of emotions in modern humans. Classic EvoEmo views (e.g., Cosmides and Tooby 2000; Tooby and Cosmides 2008) make inherent use of functionalist data and claims based on the assumption that modular, hardwired, and evolutionarily conserved emotions in their modern form (in humans alive today) reflect emotions in their ancestral form (in the first humans) with fidelity. The functions of emotions in modern humans are therefore thought to tell us something about the functions of emotions in our ancestors, thus allowing for the development of hypotheses about how those functions promoted fitness and came to be via natural selection. For example, the emotion jealousy has been suggested to arise when a relationship is threatened in order to guide behavior to reduce or eliminate that threat or fortify the relationship in question. Jealousy is held to be particularly important in the context of sexual relationships and mate selection (both of which are thought to have a clear link to reproductive success; for a review: Buss 2018).

The problem with claims about how the functions of emotions in modern humans served fitness demands in ancestral humans is that there is no way to verify that the functions of emotions in modern humans map in a one-to-one way with functions of emotions in ancestral humans. Further, no evidence exists for the hypothesized

conserved neural and physiological modularized circuits that have been hypothesized as the biological mechanisms of emotions (for reviews: Cacioppo et al. 2000; Guillery and Bujarski 2014; Kreibitz 2010; Lench et al. 2011; Lindquist et al. 2013; Kober et al. 2008; Lindquist et al. 2012; Phan et al. 2002; Siegel et al. 2018), which itself would provide a structural constraint for emotions over evolutionary time (although note that there is evidence for conserved circuits which support discrete, reflexive behaviors that may be related to emotions or used, in some studies, to measure emotion-related processes, such as eye blinks, e.g., for a review Kim and Thompson 1997). At first blush, these claims might lead to the dismissal of functionalist data as an important source of data for understanding EvoEmo. We argue that this is not the case – and in fact, that functionalist data may provide important information regarding how and why emotions evolved. But, we argue that this is only the case if functionalist data are situated within and interpreted from an alternative theoretical perspective than those frameworks traditionally levied to understand EvoEmo.

Theories of Constructed Emotion as an Alternative Framework

Constructivist approaches to emotion are an alternative approach to classic modular views of emotion, including classic EvoEmo views (for modern references on classic modular views of emotion: Anderson and Adolphs 2014; Ekman and Cordaro 2011; Izard 2009; Panksepp 2011; Shariff and Tracy 2011; Tracy and Randles 2011). Theories of constructed emotion (TCEs) are a class of theories which postulate that emotions emerge from, or are constructed from, more basic ingredients (e.g., Barrett 2017a; Boiger and Mesquita 2012; Clore and Ortony 2013; Cunningham et al. 2013; Gendron and Barrett 2009; Lindquist 2013; Mesquita and Boiger 2014; Mesquita 2010; Russell 2003). TCEs vary, to some degree, in their specification of what those ingredients are, but all propose that one required ingredient is *affect*.

Affect is an ongoing neurophysiological state that represents an organism's relationship to the environment in terms of what is good for it and bad for it and reflects activity of processes that are required for allostasis – that is, the regulation of homeostasis (for reviews on affect, Barrett and Bliss-Moreau 2009; Russell 2003). Affect is characterized by some degree of valence (hedonics) and some degree of physiological activation (arousal). Affect can be consciously experienced (as feelings of pleasantness or unpleasantness) but need not be in order to guide behavior. Moreover, affect is thought to be transformed into an instance of emotion when it is integrated with what one knows about emotions and the context in which it is occurring (in the form of concepts and language, Barrett 2011; Lindquist 2017; Lindquist et al. 2015; Wilson-Mendenhall et al. 2011; or from a predictive encoding perspective; Barrett 2017b). While the regulation of homeostasis (the foundation of affect) can occur outside of social contexts, social contexts provide robust information about affect regulation for many animals, including humans. Further, accumulating evidence from nonhuman animals and humans suggests that healthy affective processing and its development critically hinge on social context.

Evidence from human studies demonstrates that early in development, caregivers regulate infants' homeostasis and, thus, affect. For example, infants are unable to regulate aspects of their own homeostasis such as body temperature and securing nutrients and energy (i.e., food acquisition) and must rely on caregivers to perform these functions until they develop the biological capacity themselves (Christensson et al. 1992). This core regulation process is hypothesized to generalize to affective processes. Infants are highly attuned to their mothers' affective states, detecting their mothers' affect and modifying their own behavior in response (Cohn and Tronick 1983). Furthermore, infants show physiological (e.g., cardiac; Waters et al. 2014) and behavioral (e.g., reciprocal gaze, facial expressions, verbal communication, and play; Waters and Mendes 2016) coordination with their mothers, suggesting that affective coregulation between mother and infant occurs across multiple channels known to be

critical for the experience and expression of emotions. When caregivers cannot provide adequate affective feedback to their infants, infants themselves become dysregulated, exhibiting behavioral distress, further attempts to solicit a response, and elevated heart rate (e.g., Field 1984). Chronic lack of affective feedback from caregiver to infant can have long-lasting affective consequences for infants. For example, infants of mothers with depression show distress when unable to elicit facial responsiveness from their mothers, but, after sustained inability to evoke a response, withdraw from social interactions and the environment (Field 1984; Field et al. 1988).

Evidence from the nonhuman primate literature suggests that social regulation of affect may have originated with a common ancestor and that perhaps when basic biological needs are pitted against affective and social needs, the latter dominate. Seminal work by Harlow and colleagues demonstrated that infant monkeys (*Macaca mulatta*) preferred to spend time on an inanimate surrogate that provided comfort and warmth even when that surrogate did not provide food (Harlow 1958). These cloth “mothers” did not provide sustenance in the form of nutrients, but they did provide a context for social regulation: safe bases from which the infants could explore the world and to which they could return for physical comfort (Harlow and Zimmermann 1959). While these surrogates provided some essential aspects of maternal care, they were of course unable to engage in interactive social responding, which resulted in sweeping alterations to infants’ ability to perform appropriate social, sexual, and maternal behaviors (Harlow and Harlow 1965). For example, infants reared with cloth “mothers” were less socially responsive and displayed a smaller repertoire of social and affective behaviors, as well as inappropriate sexual behavior and maternal care when they became mothers themselves.

Further, recent work suggests that the building blocks of affective coregulation – namely, responsiveness and exchange of social signals – may be similar for humans and nonhuman primates. For example, both human and monkey mothers engage

in extended periods of eye contact (gaze) with their infants, which promotes social competence (Ferrari et al. 2009). Mother-infant interactions also spark the creation of other social relationships: when an infant cannot access his or her mother, he or she seeks social engagement elsewhere and participate in infant-infant relationships that are vital to the formation of social bonds and normative behaviors (Harlow and Harlow 1965).

Studies of nonhuman primates from Harlow’s laboratory and evidence from other species including rodents and humans (Caldji et al. 1998; Harlow and Harlow 1965; Harlow and Suomi 1970; Harlow and Zimmermann 1959; Hofer 1975; Kim and Cicchetti 2010; Nelson et al. 2002; Parker and Nelson 2005; Suomi et al. 1976; Tottenham et al. 2010) provide strong evidence that providing for, and meeting, only basic homeostatic needs is not sufficient for normal affective development. Being regulated by a social other appears to be critical.

Accumulating evidence suggests that social regulation of affective processes is not only critical during development but also important for adults. For example, actual and perceived assistance from others leads individuals to perceive physical challenges, such as climbing a steep slope, as less taxing (Schnall et al. 2008) and to perceive threats (e.g., electric shock) as less unpleasant and threatening (Coan et al. 2006). Close others, particularly romantic partners, can influence physiology (e.g., cardiac: Helm et al. 2014; Levenson and Gottman 1983; cortisol: Papp et al. 2013; Saxbe and Repetti 2010) and behavior (e.g., conflict initiation and resolution: Levenson and Gottman 1983), reinforcing the social component of affect coregulation and providing the foundation for the social regulation of emotions. Indeed, people differentially regulate their overt expression of emotions based on the presence or absence of social partners (for review: Wagner and Lee 1999). Moreover, emotion perception, expression, and experience vary across cultural group and language (Gendron et al. 2014a, b; for review: Nelson and Russell 2013; Russell 1994, 2003), suggesting that social context is important not only for affect but potentially

for the emergence of emotions as well (see below for further discussion of this point).

While the presence of a social partner can provide support, the absence of social support can be deleterious. When humans' social needs are not being met, the potent experience of loneliness occurs, perhaps to provide a signal to modify behavior in order to meet social needs. Critically, loneliness has significant adverse health consequences (for review: Cacioppo et al. 2015; Capitanio et al. 2014). This has led some theorists to suggest that being social – that is, being in contexts with other people and utilizing regulatory processes that include other people as important features – is so engrained in what it is to be human that it should be considered the human baseline state (Berscheid 2003). In this view, termed “social baseline theory” (for review: Beckes and Coan 2011), evaluation of affective processes outside of social contexts reflects a deviation from the norm, rather than the norm itself. Consistent evidence across animal species – specifically that monkeys also demonstrate behavioral and biological patterns consistent with loneliness (Cacioppo et al. 2015; Capitanio et al. 2014) – suggests that nonhuman animals may also have a social baseline. Considering how social context underpins affective processes in mammals, including modern humans, is but one example of how adopting a TCE for the study of EvoEmo changes how we understand the interplay between emotions and social context.

Beyond the interplay of affect and social context, the ingredients needed to transform affect into emotions – namely, shared concepts for emotions and the words (language) used to represent them – are influenced by social environment and emerge in social contexts (i.e., those with social others, human conspecifics, present; Gendron and Barrett 2018). Further, extant research suggests that emotion words are critical for shaping a discrete emotional experiences and not epiphenomenal to those experiences (for reviews Lindquist 2017; Lindquist et al. 2015). That is all to say that some of the ingredients of emotions are *necessarily* social.

Constructivist Views Generate EvoEmo Hypotheses That Can Be Tested in Nonhuman Animals

Constructivist views not only change the unit of analysis for the study of EvoEmo from individual emotions to the ingredients of emotions (as discussed above). They also inherently shift how we understand questions related to the function of emotions and thus what evidence we levy to support evolutionary claims. TCEs do not assume that emotions themselves were conserved over evolutionary time, but do recognize that the ingredients of emotions might have been (Barrett 2013, 2017a; Bliss-Moreau 2017). As a result, studying the ingredients of emotion might provide information about evolution, but there is no reason to a priori believe that the specific functions of emotion in modern humans should be the unit of analysis for the study of EvoEmo.

Moving away from studying the functions of emotions as clues to the nature of EvoEmo necessitates another empirical approach. One such empirical approach to a constructivist EvoEmo approach is to study the ingredients of emotion in nonhuman animals, mapping their topography and emergence across phylogeny. In this way, nonhuman animals represent living fossils, allowing us to develop and test specific hypotheses about how natural selection shaped the ingredients of emotion.

One evolutionary hypothesis that is consistent with constructivist views is that affect is sufficient for survival because it provides the required cues to know what is good or bad for the organism and to modulate behavior to regulate homeostasis. Affect should, therefore, be present and quantifiable in nonhuman animals. Available evidence suggests this is the case. Even very “simple” organisms – those lacking a true nervous system – are able to respond appropriately to positive and negative cues in the environment to meet fitness goals suggesting that they have rudimentary affect. For example, bacteria engage in chemotaxis – movement that is directed toward attractants (e.g., nutrient sources) and away from repellents (e.g., poisons) – in a way that reflects

homeostatic needs and environmental conditions (Crespi 2001; Webre et al. 2003; Wolanin and Stock 2004). Nervous systems provide multimodal sensory integration, movement, and behavioral coordination, as well as complexity such as social coordination. As a result, organisms like fruit flies, ants, cockroaches, and *aplysia* all have dynamic behavioral responses to regulate homeostasis even though their nervous systems are not nearly as large and complex as primate nervous systems. Behavioral and physiological findings from species with fairly simple nervous systems (small brains or no brains at all) are consistent with the idea that homeostatic and environmental signals are being integrated into affect (e.g., Abbott and Kandel 2012; Allada and Chung 2010; Bell and Sams 1973; Comer 1985; Dankert et al. 2009; Doi and Toh 1992; Moroz 2011; Ross and Keller 1998; Spieth 1974; Walters et al. 1981).

Bigger, more complexly wired nervous systems and brains allow for greater multimodal sensory integration and behavioral flexibility. The encoding of affective value in the autonomic nervous system is likely homologous in humans and nonhuman primates (for empirical evidence: Bliss-Moreau et al. 2013) and possibly other species (for a discussion: Bliss-Moreau 2017). Moreover, activity in the autonomic nervous system is thought to be one building block of conscious affective and emotional experience (Barrett and Bliss-Moreau 2009; Craig 2009; Critchley and Nagai 2012). One hypothesis is that as brains developed across evolutionary time, so too did the neural mechanisms to support awareness of these affective responses (Craig 2011; Wise 2008). This awareness may be subserved by regions of cortex that are able to integrate sensory information from the environment (exteroceptive sensory information) with sensory information from the body (interoceptive information) (Barrett and Simmons 2015; Craig 2011; Chanes and Barrett 2016). Such integration may support conscious awareness of affective states, leading to “feelings” and “moods.” Modern evolutionary theory suggests that the evolution of consciousness occurred multiple times in different lineages, meaning that awareness of affect is likely present

in other nonhuman animals, many of whom share little evolutionary history with modern humans (e.g., octopuses; Godfrey-Smith 2016, 2017). But, awareness of affect need not be a critical for affect to confer survival and fitness advantages given that it can influence behavior outside of awareness.

If only affect is necessary for survival (and reproductive success), then the ability to experience and perceive emotions must have conferred an additional benefit beyond survival for humans. One possibility is that the ability to communicate about our internal states and the behavior of others may have been critical to early social group development (for a similar argument, see Tomasello 2014). Early communication of this nature may have been about affect (e.g., “there is food at this location”; “that animal will hurt you”), and not emotions, but at some point in our evolutionary history, emotions came to be and communicating about them may have provided some new benefit. One hypothesis is that the experience of, and communication about, emotions, above and beyond affect, allowed for the formation of very large social groups that are characteristic of humans and that typically exceed optimal group size (Bliss-Moreau 2017; for a discussion of group size dynamics, Krause and Ruxton 2002). In this view, the ability to understand group members’ experiences and predict their behavior using discrete emotion concepts rather than broad affect-related concepts conferred a substantive adaptive advantage because it meant that an individual could learn about important fitness-related features of others without direct experience with them. Emotions therefore served, and serve, inherently social functions.

Emotions Serve Social Functions

The idea that emotions inherently serve social functions is precisely the theoretical space in which theorists who identify as social functionalists sit. From a social functionalist perspective, emotions play a critical role in helping individuals achieve socially relevant goals. In the years since Keltner and Haidt’s (1999) influential article,

recent theorizing in this area has predominantly focused on dyadic and group functions of emotion (e.g., Fischer and Manstead 2008; Niedenthal and Brauer 2012; Rimé 2009; van Kleef 2010; van Kleef et al. 2016, 2017), although intrapersonal (e.g., Williams and DeSteno 2014) and cultural (e.g., Mesquita and Boiger 2014) functions of emotion have also been addressed.

A core focus of social functionalists has been to investigate the ways in which emotions that arise in the context of social interactions, often referred to as “social emotions,” guide thought and behavior. These functions are thought to impact socially relevant outcomes for the individual, dyad, group, and, or, culture. A wealth of evidence speaks to how a range of positive and negative social emotions function to promote pro-social behavior and related outcomes (e.g., embarrassment: Feinberg et al. 2012; gratitude: Bartlett and DeSteno 2006; DeSteno et al. 2010; guilt: de Hooge et al. 2007; Ketelaar and Au 2003; moral elevation: Aquino et al. 2011; Siegel et al. 2014; Van de Vyver and Abrams 2015). For example, gratitude arising from receipt of a favor from a previously unacquainted stranger promotes reciprocity (Bartlett and DeSteno 2006; Tsang and Martin 2017), trust (DeSteno et al. 2010) and relational investment (Bartlett et al. 2012) toward the benefactor (for a meta-analytic review, Ma et al. 2017). These and other findings in this tradition provide a strong empirical basis for the argument that social context is a critical component of the functionality of emotion in modern humans.

Social functionalism often has evolutionary tones insofar as social functionalists draw on logic from evolutionary psychology to derive hypotheses. This occurs despite the fact that functionalist views are not inherently evolutionary in nature (i.e., an emotion can serve functional outcomes in modern humans without necessarily being given by evolution). For example, the pro-social functions of gratitude toward benefactors “spill over” to novel interaction partners (Bartlett and DeSteno 2006; Chang et al. 2012; DeSteno et al. 2010). While such patterns have been called upon as examples of evolutionarily conferred upstream reciprocity (Nowak and Roch 2007),

an evolutionary standpoint is not required to view such effects as functional in modern societal living where incidental carry-over effects of one emotional state to another context may carry benefit.

Social Functionalism Meets Constructivism in the Study of EvoEmo

Rarely, if ever, has social functionalism been linked to constructivist views of emotion. Via this linkage, the importance of social functions of emotion sheds lights on why emotions writ large (as a class, in addition to affect) came to be, rather than why specific emotions came to be across evolutionary time. The potential utility of linking functionalism and constructivism eliminates a fundamental problem inherent when social functionalism borrows logic from classical EvoEmo approaches: tenets about functions rooted in evolutionary arguments simply cannot be tested empirically in modern humans.

The synergy of social functionalist and constructivist approaches yields novel hypotheses about the evolution of emotion. If it is the case, as discussed above, that only affect is required for survival, then emotions must have served some other functions in order to have been created via natural selection. As such, a primary evolutionary question becomes: why do humans have discrete emotions at all? As discussed above, one answer to that question is that emotions generally (as a class, rather than specific emotions) supported the ability to build, ensure, and navigate complex social relationships with many individuals. A whole host of new, specific hypotheses arise from this idea. For example, modern humans with more discrete emotions may have more complex social relationships or be better able to access social resources in situations that require them for survival. Alternatively, human infants embedded in more complex social contexts may develop their emotional repertoire faster or more efficiently, and, or, their emotions may serve more functions. Additionally, the critical points in infant development in which discrete emotion concepts come online (Widen 2013) may map to

developmental challenges in which affect alone fails to promote the ability to survive and thrive.

A secondary set of EvoEmo questions generated at the intersection of social functionalism and constructivism can be asked about how specific emotions came to be across the history of modern humans. These sorts of questions may not speak to the biological origins of discrete emotions (typically the focus of classic EvoEmo views) but instead their cultural and linguistic origins (Wierzbicka 1999; e.g., see work on how emotion word usage has changed across human history; Watt Smitt 2015), opening up a new domain for the study of cultural or social evolution of emotion.

Conclusion

Approaching the study of EvoEmo from the intersection of social functionalist and constructivist views generates the hypothesis that emotions have come into existence via natural selection *because* of the unique sociality of humans (Williams and Bliss-Moreau 2016), and thus emotions and social life must be considered together to understand either.

Evolution of Female Resistance

Definition

The process by which females evolved to resist male control of mate choice, allowing females control over their own mate choice decisions.

Introduction

Classic models of sexual selection by female choice invoke conflicts of interest between the sexes. While it is in a male's genetic best interests to fertilize all of the eggs of any female he encounters, that is not necessarily in the same best interests of any particular females. Thus, female traits that discriminate between males are in conflict with the reproductive interests of any particular rejected male. There are a number of models of such conflicts and how they can influence female choice. One model views males as evolving to entice females into mating and females evolving resistance to males, as opposed to attraction to them, in order to reduce the direct costs associated with mating (Gavrillets et al. 2001). Another model suggests that females might evolve resistance to males

in order to gain indirect benefits, perhaps by allowing the female to select for males based on their ability to manipulate females or their physical strength in cases where male defense of offspring and mate might be required to select for “better genes” or material resources (Cordero and Eberhard 2003; West-Eberhard 2014).

Do Females Select Via Resistance for Antagonistic Male Traits?

There are several species where forms of female resistance have been documented. In gladiator frogs (*H. rosenbergi*), it is the males who create the nests and defend the eggs. Female courtship behavior selects for aggression in males as females test male quality. Typical courtship involves a female approaching a male and “bumping” him, a behavior that simulates elements of male-male aggressive behavior (Kluge 1981). If the male retreats, the female will leave and look for a more stalwart mate. If he stands his ground, the female will begin a massaging behavior that incites him into mating. This bumping on the part of the females allows her to assess the likelihood of the male's ability to defend her clutch. She resists his sexual approach unless he has demonstrated his quality.

In several crustacean species, there have been observations of female resistance to mate guarding. Jormalainen and Merilaita (1995) tested for sexual conflict over the duration of mate guarding in three species of crustacean (*Idotea baltica*, *Asellus aquaticus*, and *Gammarus zaddachi*) by interfering with the female's ability to resist mate guarding. Experimentally decreasing female resistance to mate guarding increased the duration of mate guarding substantially in the first species, indicating that in that species female resistance generally decreases mate guarding effectiveness. It also appears to select for large size in males. However, there was no effect of experimental interference in female ability to resist mate guarding on guarding duration in the other two species, suggesting that there was no substantial difference in male and female interests in those species or that the conflict is resolved in the male's interest.

Is There Evidence for Female Resistance in Humans?

There is clear evidence in humans that females have mate preferences for physically strong men who would be able to provide protection (Barber 1995), and it may be that those preferences are exaggerated in environments where women are at risk of male aggression or domination (Marzoli et al. 2013). However, examples of female resistance, either to avoid mating costs or to filter for specific male traits, are less clear.

Some have suggested that the commitment skepticism bias in women (Haselton and Buss 2000) is a form of filter resistance that deters females from uncommitted males. This requires males to demonstrate their willingness to commit and ability to provide benefits rather than impose costs.

Research on possible anti-rape adaptations may provide some support for resistance to avoid costs. Rape interferes with women's mate choice and risks unwanted pregnancy, being blamed by third parties, reputation damage, and psychological distress. Researchers have suggested that mate preferences for physically strong and socially dominant men as well as avoiding risky activities during ovulation (Chavanne and Gallup 1998; McDonald et al. 2015) are forms of resistance to male attempts to control female mate choices.

Conclusion

It is clear that female resistance has evolved to exert female choice in settings where male and female sexual interests diverge. Whether female resistance in humans is largely designed to avoid the costs of mating or is more specifically designed to filter between males for specific benefits or qualities (e.g., good genes) is yet to be determined.

Contest assessment strategies

Definition

The information-gathering and decision-making processes used during agonistic encounters.

Introduction

In the natural world, intraspecific competition for access to limited resources, such as food, territories, and mates, may take the form of contests, in which animals may display and/or fight to determine the winner. Animal contests result in the unequal distribution of resources and are therefore principal drivers of natural selection (Darwin 1859). Contests also form an important component of sexual selection, via intrasexual competition for access to mates (Andersson 1994), resulting in the evolution of a fascinating array of weapons used in fights. Different species show markedly different forms of contests for resources, ranging from noncontact displays to injurious or even deadly fights (reviewed in Huntingford and Turner 1987). This variation also occurs within a species, with some contests settled by display, while others escalate to fierce fighting. It is also the case that fighting for limited resources may be costly, in terms of energy use, time, risk of injury, and increased risk of predation or death (Arnott and Elwood 2009; Camerlink et al. 2015).

Early attempts to explain animal contest behavior and answer questions regarding why animals often settle contests by display rather than all-out fighting involved group selection arguments; along the lines escalated contests would result in many animals being seriously injured, and this would potentially affect the survival of the species (e.g., Lorenz 1966). However, this argument did not explain how natural selection acting on individuals can give rise to the evolution of conventional fighting. In this regard, game theory, a branch of applied mathematics, has greatly enhanced our understanding of animal contest behavior (see ► [“Game Theory”](#)). Initially developed by economists to model human strategic decision-making, biologists were quick to spot the utility of game theory for evolutionary biology. Among them was John Maynard Smith who

was the first to apply game theory to the study of animal contests, producing the now classic “hawk/dove” game (Maynard Smith and Price 1973). Related to animal contests, game theory examines how different strategies might be used by each contestant and how the winner is determined. The approach models contests in terms of costs and benefits to individuals, illustrating how individuals try to maximize fitness in contests over resources. In this modeling approach, natural selection is expected to act in such a way that a population of animals will come to adopt an evolutionarily stable strategy (ESS), which is a strategy that if employed by most members of the population, confers a higher fitness than does any other strategy. For example, in the hawk/dove game (Maynard Smith and Price 1973), contestants only differ in their choice of initial behavior between “aggressive” hawks which use escalated injurious fighting and “nonaggressive” doves which use noninjurious displays. In this game, the ESS is a frequency-dependent mixture of hawk and dove depending on the costs and benefits of each strategy. A particular advantage of the game theoretical approach has been its suitability for modeling behavior processes and formulating testable hypotheses.

The hawk/dove model set the scene for the development of more realistic game theory models of animal contests that took into account asymmetries between contestants. For example, contestants will differ in size, development of weaponry, energetic state, general physiological state, experience or position, all of which will affect the fighting ability of the animal in a contest, and together are termed resource holding potential (RHP; Parker 1974, also see entry on ► [“Anatomical Adaptations for Fighting”](#)). The most commonly used proxy for RHP in animal contests is body size/weight, with victory tending to go to the larger or heavier contestants (reviewed in Arnott and Elwood 2009). Resource ownership is a second potential asymmetry between opponents, as occurs when one animal has occupied a territory or burrow or in cases where a male associates with one or more females prior to mating. In these cases, owners typically have a higher probability of winning the encounter than do intruders. A third asymmetry concerns the value of the

resource to each contestant (reviewed in Arnott and Elwood 2008). A key point is that selection is expected to favor contestants who gather information about asymmetries and use that information in decision-making about the behavior to be used (reviewed by Arnott and Elwood 2008, 2009). The main assessment strategies that have been modeled are outlined below, together with empirical evidence, including studies related to agonistic behavior in humans.

Assessment of Fighting Ability

Assessment refers to the gathering and use of information in making decisions. Existing game theory models can be grouped into three main types that differ in the information about RHP that contestants are presumed to gather.

1. *Pure self-assessment*: Each contestant only has information about its own abilities or state and fails to gather information about its opponent. The actions of the opponent do not inflict costs, although both opponents incur a cost from their own actions. Thus, rivals persist purely in accord with their own RHP such that weaker rivals will reach their limits first and give up. This strategy is a feature of the “war of attrition without assessment” (WOA-WA; Mesterton-Gibbons et al. 1996) and “energetic war of attrition” (E-WOA; Payne and Pagel 1996, 1997) models.
2. *Cumulative assessment*: The cumulative assessment model (CAM; Payne 1998) also presumes that both opponents only have information about their own RHP, fighting until one reaches the threshold of costs that it is prepared to pay, with no direct information gathered about the opponent. However, unlike the other self-assessment models, with CAM, costs also accrue from the opponent’s actions, and superior opponents are better at inflicting costs. Thus, in the CAM, the decision to withdraw is influenced by both an individual’s own RHP, with poor-quality individual bearing fewer costs, and also the opponent’s RHP, with higher quality individuals inflicting costs

at a higher rate. As there is no direct gathering of information about the opponent with pure self-assessment and CAM, a low and similar level of cognitive complexity has been assumed (Elwood and Arnott 2012), in contrast to the assessment strategy outlined next.

3. *Mutual assessment*: These are models which involve an assessment of relative RHP difference between opponents, generally interpreted as individuals gathering information concerning the fighting ability of the opponent and comparing this against their own ability. Mutual assessment is central to the “sequential assessment model” (SAM; Enquist and Leimar 1983; Enquist et al. 1990) and the “asymmetric war of attrition” (AWOA; Parker and Rubenstein 1981; Hammerstein and Parker 1982). This strategy is more cognitively complex since contestants assess their own abilities, gather information about the opponent, and compare the two throughout the course of a contest (Elwood and Arnott 2012). An additional feature of this strategy is that contestants start with little or no information about the opponent and that early low-cost display activities provide weak information, but that later, escalated phases of the contest provide increasingly accurate information. Thus, where there is a large difference in RHP between the contestants, the decision to abandon the contest by the weaker individual will be undertaken sooner (at lower cost and requiring less escalation) than if the difference in ability is small. Mutual assessment has the selective advantage that the contestant with the lower RHP can terminate the contest as soon as it perceives its inferiority, reducing time, energy, and risk of injury from persisting in a contest that it would inevitably lose. In this regard, pure self-assessment and CAM are clearly inferior as the contestant will always incur costs up to a threshold. Mutual assessment has intuitive appeal, and our own aptitude for this strategy (outlined below) may have led researchers to generally assume such capabilities in other species without appropriately testing for the alternative strategies (Elwood and Arnott 2012). Yet, we may be in the minority of

animal species that have evolved the cognitive capacity for mutual assessment. Empirical evidence supporting each assessment strategy is provided below.

Evidence for Assessment Strategies

The three assessment strategies do not differ in predicting contest winners but in when and how the decision to give up is made. Moreover, analyses used in earlier studies failed to use the correct approach to distinguish between them (see Arnott and Elwood 2009). With mutual assessment, if the opponents differ greatly in RHP, the loser should easily discover that it is likely to lose and give up early. In contrast, longer contests should occur when contestants are evenly matched. Thus, a negative relationship between RHP difference and contest duration was used for many years to determine whether mutual assessment occurred. However, the same relationship was shown to apply to other, less cognitively demanding models (Taylor and Elwood 2003). To discriminate between the various alternatives, it is necessary to examine the effects of individual contestant RHP (typically size or weight) on contest duration (Fig. 1). With pure self-assessment, there will be a positive relationship between loser RHP and contest duration, while the winner's RHP will be weakly positively or not related to duration (Fig. 1a, b). For CAM, there is a positive relationship between loser RHP and contest duration but, unlike for pure self-assessment, the winner's RHP is negatively related to contest duration (Fig. 1d, e). This can cause confusion because mutual assessment as modeled by the SAM also predicts the same relationships (loser positive, winner negative) as for CAM. To discriminate between these alternatives, it is necessary to examine contests in which opponents within a contest are matched for RHP, with absolute RHP varying between contest pairs. With SAM, the key factor that determines contest duration is relative ability, so when the two contestants are matched, there will be no relationship with absolute RHP and duration. By contrast, with CAM, a key determinant of duration is the absolute size of the loser,

resulting in a positive relationship between pair RHP and duration.

Evidence for Pure Self-Assessment

The amphipod *Gammarus pulex* provides a clear example consistent with theoretical predictions. In this species, single males (intruders) attempt to take over females held in precopula by other males (owners). Contests occur, whereby the intruder attempts to grab the female and tug her away from the owner's hold, and larger males have an advantage over smaller males in making and resisting takeovers. In support of pure self-assessment, Prenter et al. (2006) found a strong positive relation between loser weight (a proxy for RHP) and contest duration and a nonsignificant positive relation between winner's weight and duration.

Evidence for CAM

Male-male contests between burrow owners and intruders in the Australian fiddler crab *Uca mjoebergi* provide a clear example supporting CAM (Morrell et al. 2005). Contest duration increased with increasing size of the loser but decreased with increasing winner size. Moreover, in fights between size-matched individuals, fight duration increased with increasing mean size of the competitors, this latter finding discriminating CAM from mutual assessment. In addition, Morrell et al. (2005) simulated a computer-generated population specifically modeling the predictions of CAM. In this model, contest persistence was based on individual size-determined cost thresholds and opponents inflicted costs at a rate proportional to their size (i.e., larger rivals inflicted costs at a higher rate). Thus, the duration of contest persistence of an individual was defined as (own threshold – 1/3 × size of opponent). This simulation revealed similar results to the observed data, providing support for CAM.

Evidence for Mutual Assessment

Existing research has shown a bias to assume mutual assessment even in the face of inconclusive or contradictory evidence (see Elwood and Arnott 2012). Until recently, strong evidence supporting this strategy was lacking. However,

Schnell et al. (2015), using the correct approach, provide an elegant comprehensive study involving staged contests between male giant Australian cuttlefish, *Sepia apama*, with findings consistent with mutual assessment. As advocated (Arnott and Elwood 2009), they staged both RHP (size) asymmetric contests and RHP matched contests using a setup involving males displaying aggressively to each other from either side of a large tank separated by a clear partition, thus preventing any risk of injury to the animals. Regression analyses found contest duration increased with loser RHP and decreased with winner RHP, in addition to a negative relationship between RHP asymmetry and contest duration. Furthermore, in size-matched contests, there was no correlation between absolute RHP and contest duration.

An additional approach was also used to further support mutual assessment. The approach involves assessing the motivational state of an animal in a contest by using a novel stimulus that causes a contestant to temporarily cease fighting (Arnott and Elwood 2009). The time taken to resume the contest provides a measure of the individual's motivation to fight. Using this approach, with the novel stimulus being the introduction of a female cuttlefish, Schnell et al. (2015) found that the latency to resume a contest was significantly influenced by the size of the contestants. Latency was negatively associated with the size of the focal male, meaning the greater the RHP of the focal individual, the more quickly it resumed the contest, while also being positively associated with the size of the opponent male,

meaning that the greater the RHP of the opponent, the less motivated the focal was to resume fighting. Finally, in a third experiment, the researchers found males behavioral responses varied when facing either a smaller or larger rival male. Escape behavior decreased when contesting a smaller rival, while attempted physical aggression increased. Put together, these studies by Schnell et al. (2015) provide the best evidence yet supporting mutual assessment.

Assessment of Fighting Ability in Humans

A number of studies have examined aspects of human aggression within an evolutionary context (see ► [“Dominance in Humans”](#)), including an investigation of our capacity to assess fighting ability (see entries on ► [“Assessment of Fighting Ability”](#) and ► [“Male Adaptations to Assess Fighting Ability”](#)). This is an informative approach given our highly evolved cognitive abilities, together with evidence of the importance of aggression and male intrasexual selection in human evolution (Manson and Wrangham 1991; Archer 2009, also see entry on ► [“Aggression”](#)). Visual assessment of strength in humans has been clearly demonstrated (Sell et al. 2009). In this study, the strength of males was measured by their ability to lift weights (see entries on ► [“Upper Body Strength”](#) and ► [“Upper Body Strength and Fighting Ability”](#)). Subsequently, male and female subjects rated the strength and also perceived toughness of those males from photographs. Ratings of strength were correlated with those of perceived toughness, providing evidence that raters were treating physical strength as a valid measure of fighting ability, with perceived toughness also shown to correlate with the actual number of past fights that sampled males had engaged in. Intriguingly, in addition to being able to rate the strength and toughness accurately from photographs of the full person and body alone, subjects could also do this from viewing just the face. Furthermore, Sell et al. (2010) provide compelling evidence of human adaptations to assess fighting ability from the voice. Both male and female raters could accurately assess the upper-body strength, which was correlated with perceptions of fighting ability, from voices taken

from eight samples across four distinct populations and language groups, the latter illustrating that this ability was independent of familiarity with a particular language. Consistent with the greater ancestral importance of aggression in males than females, the former were assessed more accurately than the latter. Moreover, this study provided evidence of the value of using multiple cues for assessment, with findings of increased accuracy of strength assessment when both auditory and visual cues were available (see ► [“Sex Differences in Ability to Assess Fighting Ability”](#)).

Building on the above studies, Little et al. (2015) extended the approach to actual human contests by examining the perception of male faces from paired winners and losers of individual fights in mixed martial arts sporting competitions. Observers of both sex, unfamiliar with the fight outcome, performed at rates above chance in correctly predicting the fight winner. Furthermore, separate groups of observers were also asked to choose between the two male faces based on masculinity, strength, aggressiveness, and attractiveness (women raters only). This revealed winners to be perceived as more masculine, stronger, and more aggressive than losers, while women saw the winners as more attractive than the losers. Thus, these studies demonstrate that humans possess the necessary cognitive skills to assess the risks associated with aggression by assessing fighting ability in other humans and consistent with theoretical predictions from mutual assessment (Enquist and Leimar 1983).

Animal contest theory regarding assessment strategies has also been applied to gain insights into human interstate war. Briffa (2014) outlined parallels between animal contests and human warfare, including the feature that a degree of restraint is usually present, and that a game theoretical approach may aid our understanding of these scenarios. Moreover, human war has been stated to involve a degree of information exchange about relative power between the conflicting states, akin to mutual assessment. Briffa made use of publicly available datasets to source data on war duration, outcome, and national capabilities. RHP was modeled using various measures of

state power including a composite index and size of the military. These measures had a positive effect on war outcome, validating their use as indicators of RHP. However, contrary to mutual assessment predictions, there were positive relations between both loser and winner RHP and war duration, consistent with a self-assessment process and challenging some current assumptions of human warfare.

Assessment of Resource Value

Contests typically occur over fitness relevant resources (see entries on ► [“Access to Resources”](#) and ► [“Dominance and Territory”](#)) that influence the expected benefits to be gained from winning. Game theory models illustrate that selection should favor contestants that modify their behavior during fights according to resource value, with fight costs predicted to increase with the value of the resource (Arnott and Elwood 2008). Therefore resource assessment in animal contests is predicted, and experimental evidence from a range of species supports this assertion (reviewed in Arnott and Elwood 2008).

In this regard, hermit crabs have provided a useful study system to investigate resource assessment. These decapod crustaceans inhabit empty gastropod shells that protect their delicate abdomen. A key factor in the value of the shell to a hermit crab is the size of the shell relative to the size of the crab, with individuals engaging readily in shell contests. In these interactions, one crab termed the “attacker” (usually the larger crab as size correlates with RHP) approaches and grasps the shell of the defender, the latter then withdrawing into its shell. The attacker may then engage in repeated bouts of vigorous shell rapping during which it hits its shell upon that of the defender, ending with either the eviction of the defender, allowing the attacker to take the vacated shell, or alternatively the attacker may give up without evicting the defender. The resource assessment ability of hermit crabs, *Pagurus bernhardus*, in relation to the quality of their own shells has been investigated (Arnott and Elwood 2007). One group of crabs were allocated shells that had

sand glued to their inner whorls, making them much less preferred than normal shells which had been allocated to the control group. During shell fights, if crabs in the sandy shells took the role of defender, they gave up more quickly than control defenders, revealing their low motivation to defend the low-quality resource. In contrast, if they took the role of attacker, they persisted for longer in the attack than controls, revealing their higher motivation to obtain a new shell.

Does Resource Value Influence Human Aggression?

Studies on human aggression have so far not explicitly incorporated resource value theory as applied to animal contests. That said, a number allude to its importance. For example, aggressive responses from males are more likely in response to provocations involving sexual competition or challenge, such as insulting a man’s girlfriend or showing obvious interest in her (Archer and Benson 2008). Furthermore, as noted by Briffa (2014), there is scope to incorporate resource value theory into the study of human wars, examining aspects of territory value such as food, water, fuel, and mineral availability.

Conclusion

In animal contests, selection is expected to favor information gathering regarding the likely costs and benefits of persisting in the encounter. In this regard, the mutual assessment strategy is superior to self-assessment. However, evidence is now mounting across a range of species supporting self-assessment rather than mutual assessment, yet there remains a tendency to assume mutual assessment rather than correctly test for alternatives (Elwood and Arnott 2012). The aptitude of humans for mutual assessment (Sell et al. 2009, 2010; Little et al. 2015) may have led us generally to assume such capabilities in other species.

Why then may mutual assessment be less prevalent than once assumed? It could be that only a minority of species, including humans, have the cognitive mechanisms to accurately assess fighting ability. For example, mutual assessment is

typically interpreted as a three-stage process involving assessing own abilities, gathering information about the opponent, and comparing the two throughout the contest. It remains to be understood which species have the cognitive capacity for this strategy. Furthermore, in addition to a limited capacity for gathering information, there will also be trade-offs between gathering information about the opponent's ability and the value of the resource being contested. It is also possible that mutual assessment may be costly in terms of the time and energy required to process an opponent's cues and signals, detracting from a contestant's own performance in a fight. The potential costs of assessment would be even more extreme in those cases where displays are unreliable indicators of actual fighting ability. While game theory has greatly furthered our understanding of the evolution of animal contest behavior, it is clear that there are many aspects that remain to be fully understood.

Definition

An ability to choose among alternatives

Introduction

It has always been accepted that free will, an ability to choose among alternative actions or beliefs, is characteristically human. It seems to

result from rational thought or perhaps is simply one aspect of rational thought. Because no non-human animal, we might presume, has the capacity for rational thought, none has free will either. As a result, possibilities for biological evolution of free will have never previously come up. Instead the focus has always been on how free will works in humans exclusively.

Descartes and subsequently Newton, in their mathematical descriptions of the universe, precipitated a crisis for any easy acceptance of human free will. Their approach suggested that the universe has a unique diachronic pattern. Philosophers often discuss this pattern as sequences of cause and effect. The mathematics however represents each event (for instance, the rate of change in the movement or location of any object) as an analytical function of its instantaneous context. In the twentieth century, the relativistic disposition of mass and energy and the probabilities of quantum transitions were refinements of these functions. At the scale of human behavior, however, the history of the world is uniquely determined with exceedingly high probability. The past included no alternatives and the future is predictable. Everything that has happened and everything that will happen can in principle be calculated from the present. Choices among alternatives do not occur.

As an apparent confirmation of this strict determinism, neurobiologists have argued in recent years that their results also exclude free will. The pertinent results are (1) failure to locate an area in the brain (a “module”) where neural activity is associated with “choice” or “consciousness” and (2) evidence that initiating an action precedes reporting awareness of the action by a few seconds or fractions of a second. Harris, for instance, concludes that freedom from determinism is therefore an illusion. Nevertheless, recognizing this illusion can make us more sympathetic toward less fortunate people. This recognition of course would also have to be deterministic (Harris 2012).

These neurobiological results, however, do not justify any strong conclusion about whether or not brains make decisions. It is true that many activities of brains are more or less narrowly localized.

Examples include primary sensory analysis, final motor control, memory, emotions, producing and understanding language (or species-specific songs in the case of some birds), and others. Yet there is no reason to think that some activities of the brain might, in contrast, be distributed widely. A capacity to make decisions might, for instance, depend on interactions of relatively few widely dispersed neurons, and, in addition, similar interactions might recur throughout large portions of the brain. Furthermore, the observation that reporting a movement follows initiating it indicates only that the act of reporting takes longer than the act of moving. When and where the pertinent decisions occur still elude us.

The invalidation of free will, which strict determinism entails, has deep ramifications for moral and legal judgments and for our sense of ourselves as individuals. Reluctant to accept these consequences of strict determinism, some philosophers such as Hume have thrown up their hands and accepted that, whatever else might be true, it is intuitively obvious that people routinely make practical choices. A similar position supposes that there are alternative worlds that a mind can choose. Others have proposed various cracks in determinism that could allow choices to seep into our behavior. In other words, somehow that choice can originate actions, *de novo*, despite causes or analytical continuity. The usual procedure is to suppose that each person includes a supernatural component, beyond rational explanation, a soul, a “ghost in the machine,” a “categorical imperative,” a “Dasein,” a self-consciousness, and a “self-forming act,” something that makes decisions. Kane has proposed that some inherently random component of rationality underlies freedom of action. Dennett and Gazzaniga propose that the source of freedom is the human “social arena” in which interactions with other humans provide and expect reasons for actions (Kane 1996; Dennett 2002; Baer et al. 2008; Gazzaniga 2011).

These recent approaches do not differ much from earlier ones, back to Descartes and Hume. Adventitious internal randomness (quantum or otherwise) might explain erratic behavior but not rational choice. On the other hand, an intrinsic imperative for rational or moral choice simply

displaces the origin of rational choice without explanation. Social arenas for human development can in many cases result in rationality and individual morality, but in other cases in rationalization and collective delusion, all strictly determined by context. To argue that humans can prejudicially accept the desirable alternatives, over the undesirable ones, assumes once again an unexplained moral imperative. Despite these shortcomings, attempts to understand freedom of choice have had the merit of emphasizing the two questions that must be addressed: (1) what is the source of *unpredictability* that provides an opportunity for choice and (2) what is the nature of *decision*.

Unpredictability and Decisions in Noise

A recent mathematical analysis of the evolution of communication by natural selection in the presence of noise reveals unexpected explanations for the unpredictability confronting an organism and for the organism's decisions. It provides an evolutionary context for investigating choice by supposing that all living animals (even plants) face these unpredictabilities and must make these decisions, each in its own way and within its own capabilities. Furthermore, it explains why the universe is deterministic but, for all organisms, the future nevertheless remains unpredictable. The crucial novelty of this approach is the inclusion of noise in an analysis of optimal performance in communication and perception. Noise here is anything that contributes to errors in reception of signals or in perceptions of sensations; errors in turn are responses disadvantageous to the receiver or perceiver in question; and a response can be overt or, in the case of a memory, covert (Wiley 2015, 2017, also see ► “[Evolution of Communication](#)”).

The first result of this analysis derives from signal detection theory. In the presence of noise, every receiver of any signal or perceiver of any sensation is in a double bind. Noise produces the possibility of errors, responses to signals or sensations that have net disadvantages. There are two possible kinds of errors in noise, false alarm and missed detection (errors of commission and omission). Regardless of the criteria for recognizing

relevant signals or veridical sensations, it is not possible to decrease the probability of one kind of error without increasing the probability of the other.

The second result of this analysis derives from decision theory. The utility (net advantage or disadvantage) of a receiver's criterion for response depends on the intensity of the signaler's signal, and the utility of a signaler's signal depends on the stringency of the receiver's criterion for a response. Consequently, signalers and receivers evolve jointly to a mutual optimum, a Nash equilibrium at which each party does the best it can provided the other party does likewise.

The result scales to the level of noise. One prevalent determinant of the level of noise, for instance, is the distance between signalers and receivers. At close range optimal communication consists of quiet signals and lenient criteria for response. At long range the optimum consists of intense signals and stringent criteria. In all cases residual noise persists. The evolution of communication cannot escape noise. It is inevitable.

This analysis makes it clear that decisions are ubiquitous for receivers and perceivers. Every time a receiver checks its sensors, it must decide whether or not a response (or which response) is justified. Nervous systems of all types must analyze sensations and coordinate movements, but between sensation and movement, nervous systems are primarily decision-making organs.

Noise in reception or perception is not completely predictable simply because nervous systems are not complex enough to compute the dynamics of the universe. The number of neurons in a human brain is vast, but not so incomprehensibly vast as the number of interacting particles in its environment. For a brain, indeed for any practical machine, the universe is under-specified. The universe is determined but, for any brain, it remains partly unpredictable. As a result, humans remain notoriously incompetent in predicting all the consequences even of their own actions.

Unpredictability of signals and sensations thus requires decisions. These decisions, like all else in the universe, are evidently determined. Each individual's brain, like all components of every living organism, is influenced by the genes it carries and by the environment in which it lives and develops

throughout its life. If a brain is complex enough to think (to use language in an internal dialogue), presumably it can weigh evidence for adopting more lenient or more stringent criteria for responses to any kind of signal or sensation. Whatever a brain thinks, as influenced by its genes and environment, is presumably determined, as are all other parts of the universe.

Nevertheless, a human brain cannot completely *predict* another comparable brain's activity. Explaining all interactions at any level of complexity would require a superordinate level of complexity. The collaboration among the brains of multiple people and workings of multiple other machines is making progress in understanding the general principles of how brains work. Who knows what superordinate complexity of thought might develop in the future. It remains unlikely, however, that a brain will ever completely understand and predict its own activity. Until that time, humans will continue to make decisions when faced with under-specified situations in the course of communication and perception in a noisy world.

An example of the interaction of predictability and decision in a deterministic universe is provided by chess. In this case the rules of the game are deterministic. They specify the possible moves and interactions of the pieces, in effect their "cause and effect" relationships. The number of possible sequences of moves in a game is unimaginably huge, but the number is finite (at least in versions excluding endless repetition of moves). Although the game has not been solved numerically, it is possible that there exists only one sequence of optimal moves. Humans nevertheless cannot predict this game from the outset – otherwise it would hardly be the challenge it is. Humans play the game by making decisions based on incomplete foresight. On the other hand, appropriately programmed computers can learn, indeed can teach themselves, to play with greater foresight than a human. Such a computer playing against itself or against another comparable (or more complex) computer would presumably often play the same sequence of moves.

A human cannot achieve this predictability because, with its more limited foresight, it cannot

predict winning moves of a computer. A human's decisions are nevertheless determined. For a computer to predict every decision by a human, it would require even greater complexity. Such a machine would have to learn the relevant parameters of a human's brain and its context. With anything short of such complexity, a machine must make decisions based on its own formidable foresight and its human opponents' unpredictability.

The under-specified complexity of human behavior that humans and machines fail to predict is the same as noise, errors in reception and perception, as discussed above. This complexity is determined by physical laws. Nevertheless, for any particular brain or machine, if the parameters of this complexity are incompletely known, then the resulting unpredictability (noise) requires decisions.

In such a noisy world, we can legitimately judge competence at chess based on the decisions a player makes. In a similar way, we can judge moral competence based on a person's decisions in other situations. These judgments are our own decisions, our own responses to perceptions of other people in a noisy context, under-specified and thus partially unpredictable. Holding a person accountable for decisions in particular situations might require an additional decision on our part. We might require, for instance, a supplementary judgment of the person's competence for rational thought. These thoughts would also be determined, as discussed above. Nevertheless, our only evidence for another person's thoughts comes from our noisy perceptions of that person's responses. For nonhuman animals, for machines, and in some situations for humans, including ourselves, we might withhold such judgments of rationality and accountability. All of these judgments, it is important to realize, are decisions in under-specified situations, in other words, in response to noisy perceptions. They are not an indefinite regression of determinism, just responses to pervasive unpredictability in a noisy world. Noise affects everything we do.

As for the evolution of free will, this analysis of communication and perception in noise opens the possibility for comparative studies of decision-

making and prediction. Indeed the fields of comparative psychology and ethology, as well as neurobiology, have made important progress. More could be done by including noise as well as signals in the comparative study of behavior or brains. The effects of noise only become apparent in the real, unpredictable world where a brain never knows as much as it would like about the source of the next sensation. It is important to investigate communication and perception in situations with multiple signals and receptors and variable sensations.

Evolution of Genitalia, The

Patricia L. R. Brennan
Department of Biological Sciences, Mount
Holyoke College, South Hadley, MA, USA

Synonyms

[Genital coevolution](#); [Penile evolution](#); [Vaginal evolution](#)

Definition

Genitalia are among the most variable morphological structures in animals. In several taxa, genital variation seems to be the result of sexual selection. Human males have very wide, but contrary to popular belief, not particularly long penises. Humans have also lost the penile spines and penis bone found in most primates and apes. Some studies suggest that sexual selection may have driven enlarged penis morphology in men and that reduction of the intensity of post-copulatory sexual selection may have driven the loss of the spines and baculum. However, the potential role of other mechanisms of selection has not been explored yet.

Introduction

Male intromittent organs are very diverse, and sexual selection is generally accepted as the main mechanism responsible for genital trait variation in males (Brennan 2016). More recent work has also found that variation in female genitalia is significant, if somewhat less than that found in males (Brennan 2016). Genital coevolution can result not just from sexual selection that includes female choice, male competition, and sexual conflict, but also from natural selection to make copulation feasible, and from reinforcement (Brennan 2016). Some studies have examined the potential role of sexual selection in shaping human genitalia, but natural selection is likely to have also played an important role (Dixson 2009; Brennan 2016).

Morphology of Human Genitalia

Just like other primates, human penises have large areas of erectile tissue that become engorged with blood upon erection, and the morphology of the erect penis is quite different from the flaccid penis. Penile dimensions are highly varied. Many studies have reported variation in penis size, but these have used different methods of measurement including self-reported measurements, stretched-

flaccid measurements, as well as fully erect measurements in a clinic. Variation is high within and between studies, and there appears to be no obvious correlation with body size or ethnicity (Dixson 2009). For example, a recent study of 1661 reproductively active men in the USA reported erect penis length of 14.15 ± 2.66 cm (range = 4–26 cm) and mean erectile penile circumference of 12.2 ± 2.33 cm (range = 3–19 cm, diameter = 3.88 cm) (Herbenick et al. 2014). Relative to our body size, average penis length of humans seems to fall right on the regression line for other primates, contrary to reports that human penises are disproportionately long (Dixson 2009). However, the width of the human penis is significantly greater than in other primates (Dixson 2009).

Erection brings about a significant change of length and girth and reveals a large helmet-shaped glans, similar to that found in other primate species (Dixson 2009). Compared to our primate cousins, male genitalia lack a baculum, or penis bone, and spines on the surface of the penis (Dixson 2009).

Vaginal morphology is also variable depending on age, whether women have had children or not, and their ethnicity (Pendergrass et al. 2000). Maximum width averages 5.20 cm (3.44–5.83 cm) (Pendergrass et al. 2000). Three-dimensional castings of the vaginal lumen reveal variation in its shape and size (Pendergrass et al. 2000), but sample sizes are much smaller than investigations of penile dimensions. Compared to other primates, the length of the human vagina also appears to fall right on the regression line of body size (Dixson 2012), but unfortunately, no data are available to compare vaginal width. Finally, all walls of the vagina are densely innervated, though some regions more than others.

The Role of Sexual Selection in Shaping Human Genitalia

Several studies have investigated the potential role of pre-copulatory female choice in shaping the size of the male penis. Females seem to prefer larger penises, though only when coupled with

other attractive features of body shape like taller more muscular body types (Mautz et al. 2013). Females have also been found to have a preference for a certain penis girth, based upon choice of 3-D printed models, but their preference changes depending on whether this would be for a long-term relationship vs. a one-night stand, with females preferring thicker penises for a one-night stand (Prause et al. 2015).

This preference could relate to post-copulatory female choice for larger penises. Women rate penis width as more important than length to their sexual satisfaction, and they are more likely to have vaginal orgasms when their partner had a longer than average penis (Costa et al. 2012). Therefore anticipation of sexual satisfaction may play a role in pre-copulatory female choice for penis size.

The potential role of penile morphology in sperm competition was investigated in one study that suggested that the shape of the glans penis allows males to remove sperm from previous matings during thrusting. They used model penises and vaginas to mimic removal of an ejaculatory-like fluid and showed that the penis glans could in fact cause some backflow of fluid (reviewed in Dixon 2009). However, the sperm removal hypothesis requires that females copulate with other males in a short enough period of time, to make removing rival ejaculate an important evolutionary force (typically a matter of a few hours), and there are no data that suggest this is the case. This hypothesis also ignores the fact that several primate species have a similarly shaped helmet-like glans, and this shape bears no clear association with mating system, as would be predicted if males were trying to remove sperm from promiscuous females (Dixon 2009).

The presence of penile spines and a penis bone or baculum in mammals is associated with residual testes mass, but not mating system (monogamy vs. not), suggesting their presence is associated with intensity of sexual selection (Orr and Brennan 2016). The loss of penile spines may have resulted from the shift to increased pair bonding and parental care in ancestral humans and more monogamous mating systems (McLean et al. 2011), but without knowing the

role of penile spines in mammals, this hypothesis remains speculative. Experimental penile spine removal in primates leads to longer copulation times, likely due to reduced sensitivity, and the loss of penile spines may have resulted in longer copulation times in humans compared to chimpanzees (McLean et al. 2011). Penile spines were lost in humans as a result of the loss of one regulatory enhancer that controls expression of a localized androgen receptor (McLean et al. 2011).

The loss of the baculum remains puzzling in humans. The role of the baculum in mammals, just like spines, is unclear, and many hypotheses have been suggested to explain its presence and morphology. In Primates, intensity of sexual selection measured as residual testes mass correlates with the presence of a baculum (Orr and Brennan 2016), so perhaps just as with penile spines, the advent of pair bonding and monogamy made the baculum obsolete, but again this is mere speculation given our lack of data.

The Role of Natural Selection in Shaping Human Genitalia

One possible alternative behind the large width of the human penis is that changes in vagina morphology drove changes in penile morphology (Dixon 2009; Brennan 2016). Human babies are born with large heads, almost larger than any other primate. Such large heads require a larger birth canal, both in terms of pelvic space and vaginal opening. In order for copulation to still be successful, a wider vagina would select for a wider penis so that ejaculation is still possible because friction would be maintained during thrusting. The mechanical interaction between male and female genitalia is the closest mechanical interaction between any two structures in nature, and such close coevolution is predicted to make copulation feasible.

Conclusion

Human male genitalia are unique in that they are wider than expected for our body size, and they

lack spines and a baculum, both of which are present in our close relatives. The enlarged width of the penis may have resulted from selection on males to catch up to enlarged female vaginas that could give birth to larger babies. Males that are more closely fitting the female vagina could then provide greater stimulation during coitus leading to greater sexual satisfaction in women. Women seem to have a preference for such larger penises, but it is unlikely that female preference alone would have driven morphological changes in male genital width. The loss of the baculum and penile spines may have resulted from a shift to increased pair bonding and parental care in ancient humans, and the subsequent reduction of intensity of copulatory and post-copulatory sexual selection.

[Evolution of mammalian hearing](#); [Sound perception](#); [The traveling sound](#); [The peripheral and central auditory system](#); [Vestibular system](#)

Definition

The evolution of the human ear, the auditory system, and balance.

Introduction

To have a solid understanding of the capacity to hear and listen to sounds, there must be an education of how the sound firstly travels from its source to our brain. Therefore, there will be a brief discussion of the direction of sounds, followed by an evolutionary standpoint of the middle ear's ossicles based on Reichert-Gaupp's theory and more research on the evolution of the mammalian ear.

Next will be a brief discussion of the anatomical structures of the peripheral auditory system, namely the outer (external) ear, the middle ear, and the inner ear, along with its inner most important structures, the cochlea and the otoliths.

Important for keeping balance and movement is the role of the semicircular canals. Also, there will be a brief discussion on the deleterious effects of alcohol on the balance system of the ear, otherwise known as the vestibular system.

Lastly, the central auditory system is reviewed here, with a brief literature review on the structure and function of the primary and secondary auditory cortex, as well as the molecules responsible for transducing motion into biological reactions, known as mechanosensors.

Distinguishing the Direction of Sounds

In order to understand the direction of sounds, we need to understand how sound is conducted. Usually, sound is created when an object is vibrated. The vibration travels through the surrounding medium, which is usually air, as pattern of changes in pressure which eventually is heard as sound (Moore 2001). Sound is called a pressure wave for the reason that when the molecules of the ear come closer, the pressure increases resulting in a process called compression; when the molecules move further apart, the pressure decreases resulting in a process called rarefaction (Oghalai and Brownell 2012).

According to a theorem by Fourier, the sound could be described in sinusoids, which is an analysis of complex waveforms. A sinusoid resembles the sound produced by a tuning fork,

which it is often called a simple tone, or a pure tone. Each sinusoid is called a Fourier component of the sound and a magnitude plot of the components as a function of frequency is called a spectrum. The result of a Fourier analysis is to produce the spectrum of the soundwaves by splitting the waveforms into component sine waves of different frequencies (Moore 2001; Pickles 2012). There are two important variables in each sound wave, the frequency and the amplitude or intensity (loudness). Frequency is the number of waves that passes a point in a second and is measured in cycles per second, otherwise called hertz (Hz). The amplitude or intensity is related to the magnitude of the produced movements, and is measured in decibels. The traveling sound wave relies upon the pressure of the environment which is the medium in order for the sound to be heard. This is called impedance of the medium. If the impedance is high, high pressures are needed to yield a definite velocity (see Pickles 2012, pp. 1–19).

The very first step of the hearing process is when the outer ear captures the sound waves which travel to the eardrum and cause it to vibrate. In the middle ear, the ear bones convert the airborne vibrations of the eardrum into fluid-borne vibrations in the cochlea. The traveling wave is then converted into bioelectric signals in the auditory sense cells of the inner ear (Hoy 2012).

The sound is then analyzed in the inner ear, which is responsible for performing spectral and temporal analyses of the acoustic signal. The spectral analysis is the process of extracting and defining the various frequency components of the acoustic signal. Frequency and intensity is what is otherwise called “pitch” and “loudness.” The cochlea is responsible to tease out the frequency components of the incoming acoustic signal and determine its amplitude and the temporal aspects of it. This process is the first level of auditory processing; subsequent processing takes place in the auditory pathway to the brain (Seikel et al. 2010b).

Since sound is a disturbance in the air, this causes the tympanic membrane (TM) to move. The movement, afterwards, is translated to the oval window where, based on the movement of the TM (inwards or outwards), the stapes footplate

is moved accordingly. More specifically, when the stapes compresses the perilymph of the scala vestibuli, Reissner's membrane is inflated toward the scala tympani. That is, when the fluid of the scala vestibuli is compressed, it is translated directly to the basilar membrane. In the structures of the TM-ossicle-footplate, the sound – translated into Hertz – creates a 100 Hz signal in the footplate, which in turn creates a periodic vibration to the basilar membrane where a traveling wave is initiated (Seikel et al. 2010b).

The way the sound is distinguished depends upon the frequency of the acoustic signal. High frequency sounds cause vibration of the basilar membrane closer to the vestibule, which is the basal end of the cochlea. Low frequency sounds result in a long traveling wave that reaches the apex, having to do more distance along the basilar membrane. Hence, the traveling wave distinguishes the frequency components of complex sounds because the higher frequency sounds are processed in basal regions, whereas lower frequency sounds are processed near the apex. The analysis and discrimination of lower to higher frequencies is credited to the basilar membrane. This was demonstrated on a series of experiments, performed by von Békésy (1948), that the elasticity of the basilar membrane is reduced towards the stapes rather than the helicotrema, consequently producing a stiffness gradient which, when the cochlea is stimulated, results in the creation of a pressure wave that travels from the base to the apex (Gelfand 2010, p.75). Regardless of how the traveling wave is initiated, it always travels from the base of the basilar membrane towards its apex based on the certain gradient of the membrane (Seikel et al. 2010b).

In regards to sound localization, it is through the process of binaural hearing that performance is improved in auditory tasks. Specifically, an essential task for the central auditory pathways is to analyze the auditory messages sent by the two cochleae into the auditory structures of the brain. This segregation and localization of the sound messages is significant for the separation of target signals from noisy environments. For example, sound coming from a source on the right reaches the left later than the right ear – because it has to

travel further – and it reaches it with a lower intensity. This is called the head shadow effect, that is, the further to the right the source is located, the larger the interaural differences (Avan et al. 2015). Binaural interaction takes place mainly and almost simultaneously at three levels of the brain: the superior olivary complex (SOC), the nuclei of the lateral lemniscus (NLL), and the inferior colliculus (IC) (for more on the binaural pathways of the brain see Moore 1991).

There is an evolutionary advantage of binaural processing of sounds. Information gained from this process could help detecting a predator approaching surreptitiously while the prey is engaging in a certain activity, that is, drinking water around a noisy environment. This way, the brain, by evolving and developing a refined stereophonic sound system, has contributed in the survival of species (Avan et al. 2015). Although for humans survival may not be at stake, binaural processing is helpful along noisy environments such as cocktail parties, where the listening ability depends on the type, number, and location of interfering sounds as well as the interactions of them (see Hawley et al. 2004). It is noteworthy that the increase in brain size of mammals is probably due to an increased processing ability for binaural sounds in various auditory nuclei in the brain in order to deduce the locality of sound (Manley 2010).

Reichert-Gaupp Theory

The Reichert-Gaupp theory is a theory established by Karl Bogislaus Reichert and Ernst Gaupp. Both of them are credited with the origin of mammalian ossicles of the ear. Specifically, Reichert first established the relationship between the reptilian jaw bones and mammalian middle ear bones in 1837 which was later advanced by Gaupp (World Heritage Encyclopedia 2017). The theory postulated that the malleus and incus are derivatives of the first arches of the skeletal elements of the middle ear (Takechi and Shigeru 2010). Specifically, the stapes, incus, and malleus, besides the dermal component (the goniale of Gaupp), have been confirmed to be homologous

of the reptilian columella auris, quadrate, and articular (Westoll 1944). It is noteworthy that this theory was developed before Darwin's *Origins of Species* (Takechi and Shigeru 2010).

Despite the fact that fossil records support Reichert's theory, more detailed embryological analyses and technological advances were put forward to dispute it (Takechi and Shigeru 2010). Specifically, Otto (1984) refuted Reichert-Gaupp's theory on the bases of new embryological, teratological and morphological and functional interpretation of paleontological findings. Other theories were used to oppose Reichert's theory as well such as Hanson et al. (1962) and Jarvik (1980 as cited in Takechi and Shigeru 2010).

Nevertheless, Ernst Gaupp was the first to present a synthesis of embryological and paleontological data to explain the evolution of the mammalian middle ear structures (see Maier and Ruf 2016, for a historical review of the Reichert-Gaupp Theory).

Evolution of the Mammalian Ear

Masterton et al. (1968) have aimed to identify the significant changes in the hearing capacity of the mankind evolution by comparing it to the evolution of other mammals. The results indicated that high frequency hearing (more than 32 kHz) is a trait characteristic of mammals due to the close distance of their ears, and the result of the selective pressure for accurate and instantaneous localization of the source of brief sounds. Furthermore, low frequency sounds (less than 1 kHz) is not unique to mammals; this is mostly a characteristic of humans. The researchers stressed that the lowest threshold (or overall sensitivity) is not a general characteristic of mammals nor does it differ from birds; in other words, humans have very low frequency sensitivity in sounds.

In regards of the evolution of the eutherian mammalian ear, Manley (2017) has provided an elaborative description. Specifically, he noted that more than 250 million years ago (Paleozoic era) the synapsids were separated from the stem reptiles and formed the mammals' ancestors. During

the early stages of the Mesozoic, where most evolution of the eutherian ear took place, these ancestors had a "temporary" middle ear that was connected to the lower jaw. This was later developed to a "definite" middle ear. During this period, the mammalian ancestors adopted the organ of Corti. The bone integration into the cochlea took place only in therian mammals and came before the cochlear coiling and the split of Eutheria from the Metatheria. The coiling in the cochlea resulted in the loss of the lagenar macula and, subsequently, the evolution of prestins, a motor-protein found in high concentration in the lateral cell membranes of outer hair cells which leads to increased sensitivity at low sound levels (for more about Prestin see Dallos 2008; Li et al. 2010; Zheng et al. 2002; Zheng et al. 2000).

This protein is supposed to be a mediator between the somatic electromotility in cochlear outer hair cells. These hair cells are responsible for cochlear amplification and rapid cell length changes (Franchini and Elgoyhen 2006); the transduction of mechanical activity into electrochemical activity when the stereocilia are bent (see Gelfand 2010, p.76); and compensate for the energy loss for the transmission of the traveling wave on the basilar membrane resulting in an increased sensitivity of the ear (as much as 50 dB) and an increased frequency selectivity at low intensities (Moller 2013, p.55). Franchini and Elgoyhen noted in their study that the motor-protein prestin has specifically evolved in mammals to support the mammalian adaptation of the cochlea. They concluded that their study has found evidence for the positive selection in the motor-protein prestin only in the mammalian lineage.

Additionally, signatures of positive selection on the $\alpha 10$ were found, but not on the $\alpha 9$, nicotinic cholinergic receptor (nAChR) subunits. The $\alpha 9\alpha 10$ -containing nicotinic cholinergic receptor mediates inhibitory olivocochlear efferent effects on hair cells across vertebrates (Franchini and Elgoyhen 2006). This receptor also plays a significant role in various physiological processes. For example, $\alpha 9$ is required for the normal development of the efferent synapses in the inner ear, and they serve as the unique source of

extracellular calcium for Ca^{2+} -activated potassium channels in mature auditory hair cells (Vazquez 2016). Franchini and Elgoyhen suggested that evolution-driven modifications of the $\alpha 10$ subunit most probably allowed the $\alpha 9\alpha 10$ heteromeric receptor to serve a different function to the mammalian cochlea.

A remarkable discovery made by Montealegre-z et al. (2012) was regarding the similarity in the hearing system between mammals and rainforest katydids. Specifically, these insects demonstrated to possess equivalent biophysical mechanisms for auditory processing as such of mammals, based on the three stages of collecting sound from the outer towards the inner ear. Hoy (2012) reported that these three stages are possible to have evolved primarily in insects and much later in mammals.

Further on the mammalian ear, Radojevic et al. (2015) have found evidence of the Akt isoforms, which play significant role in the mammalian inner ear, especially in the cochlea. More specifically, the kinase Akt is a key downstream mediator of the phosphoinositide-3-kinase signaling pathway, and it is involved in a variety of cellular processes. Akt is comprised of the three isoforms, each encoded by a separate gene. On their study, they have indicated that Akt2 and Akt3 enhance hair cell resistance to ototoxicity, but Akt1 does not. The researchers have highlighted the significance of these isoforms in normal hearing.

On the same vein, Warchol (2011) has identified a regenerative ability of the sensory hair cells was lost during the mammalian evolution. Specifically, Warchol argues that the regeneration failure in the mammalian ear was the result of a trade-off between phenotypic plasticity of supporting cells and sensitive high frequency hearing.

The Auditory System

The auditory system is a sensory system that is in control for hearing. It is divided in two sub-systems, namely the peripheral auditory system (i.e., outer ear, middle ear, and inner ear) and the central auditory system, that is, the auditory

nerve, cochlear nucleus, auditory cortex, auditory ascending and descending systems, etc. (Romand and Ehret 1997; Velluti 2008).

The Outer Ear

The outer (external) ear is consisted of the pinna, which consists of other structures with specific names (see Moller 2013); the ear canal (external auditory meatus); and the ear drum (lateral portion of the tympanic membrane) (Pickles 2012; Munir and Clarke 2013).

The pinna serves mainly as a collector of sound to the area of the cochlea, which is acoustically the most important part (Seikel et al. 2010a; Moller 2013). The sound is then directed to the ear canal.

The ear canal is covered by a skin that secretes wax, otherwise called as cerumen. Cerumen has an antibacterial and antifungal function, and acts as a healing agent of any small injuries that may happen in the ear canal (Moller 2013). The skin of the external auditory meatus is filled with various nerves responsible for bodily functions such as blood circulation, heart rate, and fainting.

The ear drum creates a boundary between the outer and middle ear, and constitutes the beginning of the middle ear. Also, the eardrum is divided into three ear bones: the hammer, anvil, and stirrup (Balkany and Brown 2017).

The Middle Ear

The middle ear is a space filled with air and is located behind the tympanic membrane which contains the following ossicles (bones of hearing): malleus, incus, and stapes (Munir and Clarke 2013) or otherwise called hammer, anvil, and stirrup, respectively (Hoy 2012). This constitutes the ossicular chain, which provides the way for the acoustic energy to be transmitted to the tympanic membrane and then to the inner ear (Seikel et al. 2010a). The middle ear also consists of the Eustachian Tube which forms the air space between the nose and the throat (Balkany and Brown 2017).

There are also two tympanic muscles which are attached to the ossicles: the stapedius and the tensor tympani. The Stapedius's function is to rotate the footplate of the stapes posteriorly, thus stiffening the ossicular chain. The tensor

tympani's function is to pull the malleus anteromedially, and to reduce the movement of the tympanic membrane by assigning indirect tension on it. The tensor tympani and the stapedius reduce the strength of the acoustic signal of reaching the cochlea in order to protect the inner ear from high intensity sound (Seikel et al. 2010a).

Another part of the middle ear is the Eustachian tube, which connects the middle ear and the nasopharynx, where the cranial nerve VII passes through (Munir and Clarke 2013). Its function is to allow mucous exit the middle ear and allow oxygen to enter through and out of it. It is, also, used to balance the pressure levels of the middle ear in cases where the atmospheric pressure is different such as diving and in higher altitudes (Balkany and Brown 2017).

Reichert's (1837) hypothesis regarding the middle ear in mammals has aided the understanding of the evolutionary developments of the middle ear's ossicles. Specifically, Reichert postulated that the malleus and incus were derived from cartilages comparable to the lower and upper jaw structures of the articular and quadrate. Takechi and Shigeru (2010) have found evidence from fossil records in South Africa and Russia confirming the jaw origin of the mammalian middle ear components. Additionally, the mammalian tympanic membrane is assumed to have a small dorsal part homologous to the reptilian tympanic membrane called pars flaccida, as well as a ventral portion homologous to a mammalian middle ear feature, the pars tensa.

Manley (2010) on the contrary, suggests the tympanic membrane was developed independently and that its origin is unique. Manley further elaborated that evolution in similar groups happen independently most of the time and the results from these structures could be similar. He noted that in the development of the tympanic middle ear in therian mammals, the brain became larger and a secondary palate was developed, subsequently creating a pressure system to replace the ancestral pressure-gradient middle ear (see Manley for a comprehensive review and Maier and Ruf 2016, for a historical review of the middle ear).

The Inner Ear

The inner ear is consisted of the cochlea and the balance system, otherwise called the vestibular system. Our understanding of the structure of the inner ear is based on the work of scientists who have contributed to our understanding of the cochlea (Johnsson and Hawkins 1967). Specifically the drawings of Magnus Gustaf Retzius (Jelliffe 1920) of the cytoarchitecture of the human organ of Corti showed the membranous labyrinth and it parts on various human developmental stages (Johnsson and Hawkins 1967).

The vestibular system is made up of a vestibule, which is between the cochlea and the semicircular canals. A structure called the bony labyrinth is comprised of the cochlea, the vestibule, and the semicircular canals. The fluid inside the semicircular canals is linked with movement which affects balance (Boulpaep and Boron 2005).

The Cochlea

The cochlea is a snail-shape structure, consisted of compartments in the form of a spiral. These compartments are filled with fluids. The cochlea houses the organ of Corti which is responsible for receiving acoustic information (Chang and Khana 2013). The cochlea, together with the vestibular organ, is enclosed in the temporal bone (Moller 2013). More than 15000 hair cells in the cochlea are stimulated by the vibrations of the inner ear fluid which lead to electrical signals perceived as hearing (Balkany and Brown 2017).

The cochlea's function is to separate the sounds based on their frequency so that different sound spectra activate other auditory nerve fibers. This sensory transduction is happening in the inner hair cells. The outer hair cells help to reduce friction on the motion of the basilar membrane, increase breath vibration of the basilar membrane for the lower sound intensities, and increase the frequency selectivity of sound. Frequency selectivity is decreased when the intensity of sound is increased, a phenomenon that causes the cochlea to behave in a nonlinear way. This helps to compress sounds before the auditory nerve is stimulated. This process aids to the coding of the sounds according to their intensity (Moller 2013).

Additionally, another function of the cochlea is to produce sounds directed from the middle ear to the tympanic membrane, something that consequently helps with the production of the otoacoustic emission (OAE). In essence, this is a sensitive microphone in the ear canal that records produced sounds (Møller 2013).

Regarding the evolutionary development of the cochlea, Manley (2010) suggested that a small hair-cell epithelium for hearing (basilar papilla) existed in stem amniotes, that is, archosaurs, lepidosaurs, and mammals. Fossil evidence from the coelacanth fish *Latimeria Chalumnae* supports this, suggesting that the basilar papilla seems to be the precursor of the cochlea in mammals (Fritsch 1987), a finding that is in line with Köppl's (2011) conclusion that the basilar papilla is the mammalian organ of Corti.

The organ of Corti is covered by a gelatinous and fibrous fold known as the tectorial membrane. It consists of molecules and collagens known as tectorins (Pickles 2012). These tectorins have a significant role for the hearing process (Richardson et al. 2011). The organ of Corti also is composed of a specialized structure containing hair cells. It is located on the basilar membrane and it organizes the auditory transduction (Pickles 2012).

The features of the therian cochlea, according to Manley (2017), were developed millennia ago, a process that led to the loss of the lagenar macula. This has, as a result, the structural revolution of the cochlea's physiology (Manley 2017).

Otolith

Otoliths are small particles made of calcium carbonate. The otolithic membrane is made by these otoliths, which houses the utricle and the saccule inside the vestibule (Chang and Khana 2013; Seikel et al. 2010a).

The otolithic membrane covers the utricular macula, a sensory organ consisted of hair cells and cilia. The saccule is positioned near the scala vestibule in the vestibule and is consisted of macula and the otolithic membrane. Both the saccule and utricle are connected through the endolymphatic duct implanted in the dura mater.

Because the otoliths are dense the gravitational forces help to deflect the stereocilia when the head is dormant (Hain and Helminsky 2007). When the head is moving or tilted, the otolithic membrane and the macular surface is activated, which result in the bending of the hair cells (Oghalai and Brownell 2012), hence generating a balance in the posture and in the movement.

Balance and Motion

The balance system – or otherwise called vestibular system – is a complex system comprised of various structures in the body, namely, the bony labyrinth and the membranous labyrinth of the inner ear; the cerebellum; the eyes; the brain cortex; and the muscles and joints, which are all connected to the brainstem called the vestibular nuclei (Munir and Clarke 2013; Chang and Khana 2013).

The vestibular system has two types of sensory neuroepithelium called the macula and crista ampullaris (Chang and Khana 2013). These structures contain sensory mechanoreceptors called hair cells, and they are entrenched in a neuroepithelium membrane. The first studies that were recorded on inner hair cells were by Russell and Sellick (1978). It is presumed that the job of inner cells is to disseminate the movements of the cochlear partition to the central nervous system (Pickles 2012, p. 57; Chang and Khana 2013).

Adaptation is a significant physiological property of the macula (Chang and Khana 2013). For instance, when the head is tilted for more than a few seconds, the bent hair cells and the depolarized membrane potentials return to normal. Consequently, this process assigns to the hair cells the property of being responsive to any movement of the head (Oghalai and Brownell 2012).

Bony and Membranous Labyrinth

The bony and the membranous labyrinth is a complex balance organ in the inner ear, which is a part of the peripheral vestibular system. The bony labyrinth consists of the cochlea and the semicircular canals, and it is filled with a fluid similar to the cerebral fluid, called the perilymph (Hain and Helminsky 2007), which is used by the

perilymphatic duct into the subarachnoid space (Chang and Khana 2013).

The membranous labyrinth consists of the sensory epithelium and is embedded in the perilymph inside the bony labyrinth. Inside the membranous labyrinth there is a fluid which is called the endolymph (Chang and Khana 2013). The membranous labyrinth also consists of the utricle, the saccule, and the lateral, superior, and posterior semicircular ducts (Chang and Khana 2013). Each structure contains the macula – a sensory neuroepithelium. The macula of the utricle senses horizontal movement whereas the macula of the saccule senses vertical movement. The utricle and saccule sense the movement of the head in space and they respond to linear acceleration, forces of gravity, and the tilting of head (Chang and Khana 2013).

Semicircular Canals

The location of each semicircular canal is vertical to the other canals on the same side and belongs to the same side of the body with the opposite canals (Chandrasekhar 2013).

The three semicircular canals sense the turning motion of the head. The otolithic organs (utricle and saccule) then analyze the motion of the head and create a nerve signal to the brain to indicate movement (Munir and Clarke 2013). A structure named semicircular duct compose the kinetic labyrinth that perceives the acceleration or rotation of the head. At the end of each semicircular duct there is a structure called the ampulla, which contains the crista ampullaris, covered by a gelatinous substance contained with hair cells, called the cupula (Chang and Khana 2013). Based on the rotational motion of the endolymph, the cupula bends the hair cells which fire afferent fibers and transfer the movement information in the brain (Chang and Khana 2013).

Alcohol and Balance

Alcohol intoxication has devastating results in the organisms in many ways. Besides its negative effects in the postural sway (Woollacott 1983), alcohol intoxication also affects the oculomotor

system. Based on a study from Nieschalk et al. (1999) it is evident that the vestibule-cerebellum is, also, affected. Consistent with the research of Ikeda et al. (1980), small doses of ethanol interfere with the synaptic transmission in the lateral nucleus (LVN) monosynaptic and polysynaptic II neurons.

Additionally, Modig et al. (2012b) demonstrated in their research that postural control is significantly affected. They highlighted the fact that ethanol consumption causes destabilization in lateral motion than in anteroposterior motion and that intoxication decreases adaptation mechanisms regarding stability control.

When alcohol is taken in high amounts, the cupula in the semicircular canals is affected and becomes lighter than the endolymph leading to the buoyancy hypothesis (Fetter et al. 1999) and subsequently to a process called positional alcohol nystagmus (PAN) and rotatory vertigo. When the gravitational vestibular cues are compromised, visual information are used instead (Hafstrom et al. 2007). Essentially, alcohol intoxication causes a multifaceted deterioration of balance and movement (Modig et al. 2012a).

Evolutionary Perspective on the Vestibular System in Mammals

From an evolutionary perspective, Beisel et al. (2005) have identified a protein called osteopontin using immunocytochemistry in the otoconia (a structure inside the utricle and saccule of the ear). This protein is suggested to be a component protein of the mammalian otoconia. The researchers concluded that vestibular ear evolution appears to be linked to the enrolment of specific genes into an existing network of gene expression (Beisel et al. 2005).

Auditory Neurobiology

The physiology of the auditory nervous system was extensively reviewed more in animals than humans. It is consisted of ascending and descending systems that connect a link between the ear and the auditory cerebral cortex. Axons from the ear link to the cochlear nucleus neurons

connect to other nucleus in higher locations until they reach the cerebral cortex. Then, these neurons descend from the central structures to the nuclei of the ear distance (Moller 2013).

There are different pathways known as classical ascending pathways and nonclassical or adjunct systems. There are, also, specific nuclei between the auditory nerve and the primary auditory cerebral cortex found in the classical ascending pathway (Demanez and Demanez 2003). These are the cochlear nucleus (CN), the central nucleus of the contralateral inferior colliculus (ICC), the lateral portion of the ventral division of the contralateral medial geniculate body (MGB), and the superior olivary complex (Moller 2013). These nuclei are responsible to analyze the acoustic data through theory synaptic transmissions and their position in the brain (Moller 2013; Velluti 2008).

The function of the auditory nervous system is the so-called frequency selectivity. The frequency selectivity of the basilar membrane handles the frequency tuning of the auditory nerve cells and the cells in the ascending auditory pathways. According to the characteristic frequency, the nerve fibers of the auditory nerve, the cells of the auditory nuclei, and the cells of the auditory cerebral cortex are arranged anatomically. This is known as the tonotopic organization (Moller 2013; Polley et al. 2014).

Primary and Secondary Auditory Cortex

The auditory cortex is responsible for the processing of sound based on the many connections that handle auditory information (Moller 2013; Hackett 2015). It is noteworthy however that the complete anatomy of the auditory cortex is still to be understood and known completely. The lack of consensus between researchers regarding the exact anatomic positions of the auditory parts has contributed to the lack of the full understanding of the auditory cortex and the unfolding of a comprehensive tonotopic map (Moller 2013; Saenz and Langers 2014).

Based on studies that used MRI techniques, the location of the primary auditory cortex was found on a region on the medial two-thirds of Heschl's gyrus, linked to Brodmann's area 41 (Pickles 2012; Wasserthal et al. 2014; Moller 2013). The only

regions successfully mapped are frequency (Isaa et al. 2017; Wolak et al. 2017), modulation rate (Lithari and Weisz 2017), sensory tuning bandwidth (Saenz and Langers 2014; Wang and Eliades 2017), and sound intensity (Bilecen et al. 2002).

Regarding the secondary auditory cortex, Moller (2013) suggests that it responds to other stimuli, such as touch and vision. Several research suggest that there is a connection between the visual and the auditory cortex (Chen et al. 2013) and multimodal sensory interaction (Hosokawa et al. 2017).

Mechanosensor

Mechanosensory molecules are molecules which interact with other molecules and influenced by mechanical forces that may engage in biological reactions (Shen et al. 2017). This leads to a process known as mechanotransduction where based on mechanical stimuli there is a transduction into electrochemical signals and cellular responses (Bavi et al. 2017). They also work as molecular reporters inside the cells connecting mechanical stimuli to intracellular signaling events (Bavi et al. 2017).

Research suggests that the evolution of the mechanosensors took place independently (Delmas and Coste 2013). More insight on mechanosensors was based on the research of Kita et al. (2013) studying the birth of a mechanosensor and Kung's (2005) unifying principle for mechanosensation.

Conclusion

The most important structures of the ear have been reviewed. There was also a review of the evolution standpoint of the mammalian ear, and how it was developed to be as it is. Various structures of the inner ear work together to provide posture equilibrium. Not only the ear, but the neurobiology of the brain contributes to keep a person's balance in check.

not always the case, and there are numerous possible variations. For example, many animals possess the sexual organs of both genders either simultaneously or at different times of their lives. Earthworms first mature as males and then lay eggs and fertilize those after copulating with another male. Despite both animals having the male gender at the time of copulation, biologists describe such cases as hermaphroditic rather than homosexual. Clownfish start their life as males and develop into females when the group matriarch dies. In this case, biologists refer to them as sequential hermaphrodites rather than transgenders. However, nonreproductive sexual behavior has been observed between members of the same sex (homosexuality, HS) in numerous species including our own. So, is “true” HS common in nature, and why?

Biological exuberance

Definition

Study of transmission of same-sex sexual behavior across animal species and humans.

Introduction

Sexual behavior takes multiple forms across organisms, and although it has evolved for reproduction, it also serves other social purposes. The evolution of sex has also led to sexual dimorphism, meaning that there are morphologically and behaviorally distinct male and female genders. Across species, males usually have sex with females (heterosexuality); however, this is

Natural History of Homosexuality

In birds and mammals, there are numerous reports of homosexual behavior, which may or may not involve a sexual act, but can include courtship, pair-bonding, and coparenting. These have been observed in geese, flamingos, gulls, oystercatchers, warblers, dolphins, deer, zebras, giraffes, and others (Bagemihl 1999). At least 93 species of birds engage in HS (MacFarlane et al. 2010). Same-sex mounting is commonly observed in a wide variety of mammals such as gazelles, sheep, and elephants, and this has been attributed to expression of dominance or hormonal malfunction during rut (Bagemihl 1999).

Homosexual sex is particularly developed in primates. Interestingly, HS is more predominant in primate lineages more closely related to humans than in more distant taxonomic groups such as lemurs. In new-world monkeys (platyrrhines), such as squirrel monkeys, homosexual behavior seems limited to play and dominance interactions. In contrast in apes and old-world monkeys (catarrhines), homosexual sex is common and complex, involving consort bonding, reconciliation, tension regulation, and alliance formation (Vasey 1995). Among apes, pygmy chimpanzees (bonobos) are famous for the large variety of sexual acts that they perform,

including genito-genital rubbing, fellatio, and manual masturbation across all genders (De Waal and Lantin 1998). Bonobos are bisexual, and this is thought to contribute to group cohesion (De Waal and Lantin 1998). Common chimpanzees also engage in homosexual sex, for example, with about a third of mountings occurring between males (Bagemihl 1999) (Fig. 1). In mountain gorillas, which live in groups dominated by fewer males than in chimpanzees, sexual behavior between females is widespread (Grueter and Stoinski 2016). Other catarrhine examples of HS include baboons, macaques, and langurs (Bagemihl 1999). However, after bonobos, homosexual behavior is probably most common in humans and has been documented by anthropologists worldwide, across cultures and time periods (Table 1).

In all these examples, bisexuality may be the norm, as those individuals involved in HS often also take part in reproductive sex. However, there are also numerous exceptions, for example, about 15 % of male graylag geese are strictly homosexual (Kotrschal et al. 2006). There is increasing evidence that HS is common in nature; however, scientists and the public at large have only learned about it relatively recently, perhaps because the reporting of such behaviors had been previously censored due to societal and religious taboos.

Is Homosexual Behavior a Darwinian Paradox?

Homosexual behavior has often been considered a “Darwinian paradox.” This is because, intuitively, a genetically influenced focus on nonreproductive sex to the detriment of reproductive sex should reduce evolutionary fitness (i.e., reduce an individual’s number of descendants), and any such genetic variants should eventually go extinct (Kirkpatrick 2000). However, twin studies indicate that heritability of homosexuality is ca. 30 % in men and up to 60 % in women (Kirk et al. 2000). Note, however, that these values may be inflated, because twin studies generally estimate the broad-sense heritability, which includes several components of genetic variance, as opposed to the narrow-sense heritability, which only includes the statistically additive effects of genes. Nevertheless, the fact that there is some heritability of HS indicates that there is a genetic component underlying such a widespread behavior. Thus, the discrepancy between simple evolutionary expectations and the observed nature and prevalence of HS warrants explanation; but is homosexuality really an evolutionary paradox?

Among variable traits, homosexual behavior stands out, because the fitness consequences of preferring same-sex sexual partners seem obvious

E

since these pairings never result in offspring. Also, widespread cultural taboos that consider HS to be “unnatural” likely draw extra attention to it. However, there are at least two reasons why the seeming paradox of HS might be an illusion. First, the fitness consequences of HS are largely unknown and may be greatly overstated. Second, sexual preference is not a binary trait with clear homosexual and heterosexual states. Rather it is a continually variable quantitative trait, maybe involving the interactions of many genes (Bailey et al. 1993), and ranging from exclusively homosexual attraction through all degrees of bisexuality to exclusively heterosexual attraction (Sell 1997); for simplification, Kinsey scored sexual behavior from 0 (strictly heterosexual) to 6 (strictly homosexual) (Kinsey 1948). It is not unusual for continuously variable traits to have fitness costs at the phenotype extremes rather than in the middle range (Lande 1976).

HS can only be a paradox if the genetic factors that predispose individuals towards homosexual

behavior have real fitness costs. Although there are reasons to doubt whether there are actual fitness costs to homosexuality, quantifying fitness in long-lived natural populations is extraordinarily difficult (Kingsolver et al. 2001). First, in social species nonreproductive sexual behavior is common even in heterosexual pairings. This is especially true in humans, where females remain continuously sexually receptive throughout the nonfertile phases of their cycle, and even while pregnant (Gangestad and Thornhill 2008). In humans and other primates, nonreproductive sex (including homosexual sex) is thought to have important social implications (De Waal and Lantin 1998; Gangestad and Thornhill 2008; Vasey 1995). Thus, there may also be fitness costs to extreme heterosexuality due to reduced sociality, as well as fitness costs to extreme homosexuality due to lost mating opportunities. If so, some intermediate phenotype may be optimum. Second, there is some evidence that the genetic variants that predispose to HS increase fitness in

those who have the genes but not the phenotype. Support for this has been found in genetically identical twins where one is homosexual and the other heterosexual. In such twins, the heterosexual members have a greater number of opposite-sex sexual partners compared to identical twins who are both heterosexual (Zietsch et al. 2008). In this scenario, there is no evolutionary paradox so long as the lost reproductive success of homosexuals with the predisposing genes is balanced by increased reproductive success in heterosexuals with those same genes.

Furthermore, the fact that HS is not entirely heritable also points towards significant amounts of phenotypic variance being nongenetic and due to environmental variation (maybe up to 70 % in men; (Kirk et al. 2000)). Nongenetic variation needs little or no adaptive explanation even if there are fitness costs. This variance in quantitative traits is generally known to be a combination of direct effects of environment on individual phenotypes plus developmental noise, much of which may be practically unavoidable (Lande 1976).

Finally, even if there have been real fitness costs to homosexual behavior, this alone does not make the behavior unique or in particular need of biological explanation. Most traits that vary within humans are heritable and many of these will have fitness differences according to trait expression. For example, stature in humans is highly heritable (90 %) (Macgregor et al. 2006), and taller (but not extremely tall) men have greater reproductive success (Pawlowski et al. 2000). Similarly, physically attractive people have greater reproductive success than unattractive people (Jokela 2009). Yet, neither biologists nor the general public wonder why there are still short, less attractive people. It might be supposed that there is excess focus on HS compared to, say, stature, because the effects on reproductive success are more direct. However, this is not necessarily the case. For example, erectile function/dysfunction is a variable trait with clear reproductive implications. Yet, there has been almost no interest among researchers or the general public in why natural selection has not eliminated erectile dysfunction (Cellerino and Jannini 2005). The long-term maintenance of genetic and phenotypic

variation in quantitative traits despite stabilizing selection or fluctuating directional selection has long been recognized (Lande 1976; Lande 2008), and it is likely that the focus on HS as an evolutionary paradox is largely driven by cultural taboos against the behavior, rather than any real unique biological perplexity.

Biological Models of the Prevalence of Homosexual Behavior

The seeming Darwinian paradox of homosexual behavior has led to the development of several biological models to explain its prevalence. Most models fall into two broad categories: genetic and epigenetic models. Genetic models typically explain the persistence of a hypothetical “HS” gene variant (allele) through some indirect evolutionary advantage for that variant. Epigenetic models explain homosexual behavior as a result of heritable changes in gene expression patterns due to chemical modifications that occur to the DNA of developing organisms. These models each make clear predictions; however, there is only limited support for any of them.

Kin altruism selection. This model is based upon William Hamilton’s kin selection theory and suggests that homosexuals forego their own reproduction in order to altruistically aid in the rearing or reproductive efforts of relatives (Kirkpatrick 2000). Kin selection theory only predicts altruistic behavior when the reproductive benefits to the recipient are greater than the product of the cost to the altruist and the degree of relatedness. Because the costs of completely foregoing reproduction are quite high, this model predicts that only individuals of low phenotypic quality with low personal reproductive potential should adopt the strategy. It also predicts that the behavior will be more common in males because of the greater variance in male reproductive success. There is little direct support for the kin selection model. Also, it is not clear why foregoing reproduction to aid relatives would necessitate HS (Kirkpatrick 2000).

Overdominance selection. Overdominance selection proposes that men who are heterozygous for a hypothetical “HS” allele are heterosexual and have increased fitness over homozygotes for the “HS” allele (who are homosexual), as well as over homozygotes for the “non-HS” allele (who are also heterosexual). The same applies to women. In this scenario, the increased fecundity of heterozygotes maintains the “HS” allele in the population at a frequency that is determined by the relative fitness of the three genotypes. With overdominance selection, it is expected that the “HS” gene will be found on a nonsex chromosome (autosome), because it is easier to maintain overdominance polymorphisms at equilibrium on those autosomes rather than sex chromosomes (Gavrilets and Rice 2006). There is currently scant evidence for the overdominance selection hypothesis.

Sexually antagonistic selection. In sexually antagonistic selection, a hypothetical “HS” allele would result in an evolutionary cost when expressed in men (i.e., they would have fewer offspring) but would be counterbalanced by an advantage when expressed in females (i.e., more offspring), or *vice versa* (Gavrilets and Rice 2006). In this scenario, it is hypothesized that an “HS” allele would be either masculinizing or feminizing when expressed in either sex. A masculinizing “HS” allele would increase the fitness of males, but decrease the fitness of females by causing HS, and a feminizing “HS” allele would do the opposite. Under the sexual antagonistic model, it is expected that genes influencing HS would be found on the X chromosome more often because there are a wider range of relative fitness scenarios under which polymorphism can be maintained compared to the autosomes, and this is one possible way in which this model can be distinguished from overdominant selection (Gavrilets and Rice 2006). Limited evidence in support of the model comes from the finding that markers on the X-chromosome influence male homosexuality in humans (Hamer 1993).

Bisexual advantage. Another model is proposed here for the maintenance of homosexual

behavior based on the idea of stabilizing selection or fluctuating directional selection; this new model is called “bisexual advantage.” This model extends aspects of homosexual alliance formation discussed above in primates, along with a quantitative genetics approach to trait evolution. Sexuality is a continuously variable and heritable trait that ranges from exclusively homosexual attraction to exclusively heterosexual attraction. Numerous genetic loci would contribute small additive amounts to the overall heritability of this quantitative sexual trait. It is hypothesized that the optimum trait value with respect to reproductive fitness is intermediate and thus in the bisexual range (maybe between Kinsey’s 1–3 scores). Individuals with fully homosexual attraction (Kinsey’s 6 score) would fail to reproduce and be selected against, while individuals with fully heterosexual attraction (Kinsey’s 0 score) would also have fewer offspring. This may be because such individuals are poor at forming social alliances (Kirkpatrick 2000), or it may be for some yet unknown reason. Indeed, such a pattern where both phenotype extremes are disadvantaged is thought to be the most common among quantitative traits and is due to stabilizing selection or fluctuating directional selection (Lande 1976; Lande 2008). The bisexual advantage model predicts that (i) some degree of bisexual attraction is more common than exclusive homosexual or heterosexual attraction, (ii) sexual attraction is fluid and changes depending upon social context (i.e., the environmental component), (iii) many genetic loci weakly influence sexual attraction, and (iv) there are no genetic loci that strongly influence sexual attraction. The bisexual advantage model is perhaps the most conservative genetic explanation for the persistence of homosexual behavior because sexuality would then follow the pattern of the vast majority of quantitative traits where intermediate phenotypes are favored (Lande 1976). Note that this model is compatible to a degree with the sexually antagonistic model, if (i) possessing one copy of a “HS” allele contributes to some, but not

exclusive, homosexual behavior and (ii) this allele goes to fixation in the population (i.e., every individual of the population has a copy of this allele in their genome (Savolainen and Lehmann 2007)).

There is some behavioral as well as genetic support for this bisexual advantage hypothesis. First, good estimates of the frequency of bisexuality do not exist; however, the majority of human and nonhuman animals that participate in homosexual sex also participate in reproductive sex (Kirkpatrick 2000; Vasey 1995). Second, the expression of homosexual behavior is known to be condition-dependent in humans. For example, having spent time in the US Navy or in a British boarding school increases the likelihood of having had homosexual experience (Kirkpatrick 2000). Finally, genomic surveys looking for genes that influence sexual attraction have failed to find any loci that strongly predict homosexuality (Sanders et al. 2014). Instead, genome-wide scans have identified relatively few loci associated with HS, each with relatively small effect, leaving the majority of the heritability of homosexuality unexplained. This is the expected pattern if most of the heritability is contributed by loci with too small of an effect to be detected in genome-wide scans (Yang et al. 2010), suggesting that sexuality is a quantitative trait, and the majority of loci influencing sexuality are yet to be discovered.

Paternal and maternal effects. In an epigenetic model of HS, so-called epigenetic marks (changes in DNA packaging such as DNA methylation or histone tail modifications) influence sensitivity to androgen hormones by the developing genitals and brains, and therefore also influence gender preference and identity (Rice et al. 2012). In animals such as humans, male and female sex chromosomes (XY and XX, respectively) have characteristic epigenetic marks that canalize development accordingly. When discordant epigenetic marks are passed trans-generation, a child may develop a cellular mosaic whereby genital development will match the appropriate sex chromosome but brain development for sexual

preference will be canalized towards the opposite gender by the epigenetic marks. Put simply, a mother may pass onto her son discordant epigenetic marks causing the development of female sexual preference and resulting in male HS. The same logic applies to the father of a lesbian daughter. This epigenetic model of HS has advantages over genetic models: It is compatible with the relatively low concordance of HS in identical male twins (30 %; (Kirk et al. 2000)) and with the fact that genomic association studies have failed to find strong genetic markers for HS (Rice et al. 2012; Sanders et al. 2014). The model has also clear testable predictions, although the practicalities of such studies would be impaired by requirements to work with postmortem or fresh human stem cells (Rice et al. 2013). Nevertheless, those predictions include: (i) there are XX- and XY-specific epigenetic marks in the stem cells of developing heterosexuals; (ii) there are XX- and XY-discordant epigenetic marks in the stem cells of developing homosexuals; and (iii) some of these discordant epigenetic marks are trans-generationally inherited and therefore will be shared with higher frequencies by identical twins when at least one is HS, but not necessarily the other one (Rice et al. 2013).

Conclusion

Homosexual behavior is common throughout the animal world and has often been considered an evolutionary paradox. The existence of the supposed paradox is likely a confluence of the assumption that those who engage in HS fail to reproduce, coupled with cultural disapproval of homosexual behavior. Some of this confusion may also stem from the fact that most researchers have considered sexuality to be a binary trait with either homosexual or heterosexual trait states. If sexual preference is a continuous trait influenced by many different genes of small effect, or some epigenetic marks canalizing a “mosaic” development, then the persistence of homosexual behavior is not particularly surprising. In fact, it may be

the case that some degree of bisexuality is actually an evolutionary optimum phenotype in many species, including humans.

Cooperation; Human cooperation; Large-scale cooperation; Prosociality

Definition

There are different evolutionary mechanisms that explain human large-scale cooperation (which is so rare in animal kingdom) even with genetically unrelated people.

Cooperation has adaptive importance as it increases the chances of hunting success and access to resources through the establishment of coalitions in almost all primates including humans

(Tomasello 2000). Cooperative interactions are also of vital importance to the members of the group in terms of survival advantage since the resources obtained by the group are closed to those who do not contribute to the public good as a cooperative interaction. That is why cooperation can be considered as a mechanism that emerged as an evolutionarily stable strategy. Similarly, our cognitive architecture is thought to evolve in order to make cooperation possible. For instance, the emergence of a number of cognitive mechanisms such as language or sense of morality is thought to have emerged because they have a role to enhance cooperation in groups (Tomasello 2016).

If we look at the evolution of human sociality more specifically, the first cooperative interaction emerges in the interaction between mother and child as a result of the attachment relationship. In other words, caring for the offspring in terms of physical and psychological bonding occurs with the help of hormones such as oxytocin (Nelson and Panksepp 1998), and it might be considered as the origin and simplest version of human sociality. Second, this cooperation is extended to close relatives (Hamilton 1964). The rationale here is that helping relatives is actually an indirect investment in our own genes because we share certain genes with our relatives.

However, human sociality can go beyond kinship relations in contrast to other primates. Human beings interact and cooperate with genetically unrelated people and can even help by endangering their own lives. The primary evolutionary mechanism that explains the cooperation among genetically unrelated people is the principle of reciprocity (Trivers 1971). Reciprocity can take place directly or indirectly. In the case of direct reciprocity, friendship relationships are defined and the person wants to help someone else directly and to guarantee the potential provision they receive from the person in the future. In other words, if I help you, I can see the same help from you and this expectation of helping in return can explain why friendship among genetically unrelated people emerges in human animals. In indirect reciprocity, because of the reputational concerns of the person, the person helps another

person and indirectly increases the likelihood of getting help from others who witness this help. For example, helping a beggar walk down the street can be taken as an example because helping the beggar is not about expecting direct help from the beggar. On the contrary, this help gives a sign that she can be a reliable cooperation partner to other people in the vicinity, and this behavior increases her reputation and increases the likelihood that she will be helped by other members of the group when she falls on hard times in the future.

However, large-scale cooperation with genetically unrelated people without any kind of reputational concerns is not easily explained by standard evolutionary mechanisms. To solve this evolutionary puzzle, supernatural punishment hypothesis was proposed in order to understand why people help others in anonymous and one-time interactions (Johnson and Krüger 2004). According to this hypothesis, human surveillance is not enough to observe every situation that violates the norms of large-scale cooperation (such as “do not kill anyone,” or “do not steal”), and thus unable to punish every norm transgression, and thereby unable to deter future moral violations. However, belief in the existence of a supernatural entity that can observe and punish every norm transgression can sustain large-scale cooperation and deter free-riding. In other words, the idea of supernatural punishment contributes to the large-scale human sociality as a mechanism for interpersonal cooperation. This approach argues that the emergence of religions, especially of religions with big and moralizing gods, is a fundamental factor that extends human sociality and allows us to spread all over the world.

In conclusion, it is possible to say that human sociality, in part, is based on the evolutionary process. This mechanism first appears in mother–child interaction and the mother is cognitively equipped for protecting her child from potential harm. Likewise, relatives with similar genes can also help each other by protecting each other, because helping relatives is actually an investment in their own genes. People who do not have any genetic similarities help each other in regard to the mechanism we call reciprocal

altruism: if I help you, one day you can help me (direct reciprocity), or someone else in society can help me (indirect reciprocity). However, large-scale cooperation without any kind of reputational concern, which is commonly seen in human societies, still awaits a more systematic explanation. The supernatural punishment hypothesis might be a good candidate for solving this puzzle.

Evolution of Humor, The

Mary Louise Cowan
Regent’s School of Psychotherapy and
Psychology, Regent’s University London,
London, UK

Humor can broadly be defined as verbal or non-verbal behavior which is perceived as funny and produces laughter or amusement in others (Martin

2007). Humor is integral to human interaction and is usually pleasurable to engage in (Meyer 2000), yet the explanation for why humans have evolved a sense of humor remains unresolved. Humor is complex, difficult to produce, and highly risky (Polimeni and Reiss 2006). These are qualities that might typically be associated with an adaptive trait that is integral to our survival and therefore justifies its own costly existence. However, there does not seem to be an obvious or immediate survival benefit from humor. Despite this, humor and laughter have been observed around the world suggesting a universality which is typically seen in adaptive traits. Similarly, humor and laughter appear to be innate as babies begin to laugh at the earliest stages of life (Sroufe and Wunsh 1972). Babies of 4 months of age have been observed laughing at tactile events (e.g., tickling) and by 7 months have been observed laughing at incongruities (Sroufe and Wunsh 1972). Further evidence illustrates that this is not just the product of learning social cues from parents, which strongly suggests an innateness to the sense of humor (Mireault et al. 2015). The adaptiveness, universality, and innateness of the sense of humor can most likely be explained by the social bonding function it has, which helps us to initiate and maintain friendships and relationships (Li et al. 2009). Observations that behaviors which produce laughter can be seen in other great apes provide very compelling evidence that this is the case (Provine 2017). This chapter will briefly consider what humor is before reviewing the likely origins of this behavior and the theories behind why humor has evolved. The history of the evolution of humor will first be discussed to better understand where the sense of humor may come from, which makes it clear that there are strong evolutionary origins to this complex behavior.

What Is Humor?

When it comes to determining what actually makes something funny, humor researchers largely agree that incongruity and unexpectedness are critical components (Gervais and Wilson

2005). Shultz and Horibe (1974) demonstrated this with the following joke; “Doctor, come at once! Our baby swallowed a fountain pen.” “I’ll be right over. What are you doing in the meantime?” “Using a pencil.” This example contains an incongruity between the doctor’s question and the parents’ answer, which is unexpected but can be resolved by the audience. However, unexpected and incongruous events may not always be considered humorous. For example, a woman may try to amuse her baby by wearing a red nose and behaving like a clown. For the baby, this may be very unexpected and not typical behavior of their mother and they may laugh as a consequence. However, if the woman dressed up as a clown at a funeral it would no longer seem funny even though it is unexpected and incongruous; rather, it would be inappropriate and likely offensive.

The concept of what makes something funny has more recently been extended in the Benign Violation Hypothesis proposed by Warren and McGraw (2015). This hypothesis suggests that in order for something to be funny it must contain a violation, for instance the mother with a red nose acting like a clown. But this must be combined with a benign scenario to ensure that it does not present genuine danger or a threat (as this may no longer be funny) (Warren and McGraw 2015). If an event meets these criteria, where it presents a benign violation, it may then be considered humorous. This definition offered by the Benign Violation Hypothesis means that the concept of humor may therefore extend to a wide range of behaviors; from complex verbal humor to play fighting and tickling. Indeed, tickling captures the essence of benign violation because it has the appearance of a physical threat (violation) but it is not harmful (benign) and it therefore tends to elicit laughter from the recipient (Provine 2004; Gervais and Wilson 2005; Polimeni and Reiss 2006). Gervais and Wilson (2005) suggest that the majority of research on humor tends to focus on adult humor but a behavior such as tickling may actually help us to understand the evolution of humor much more clearly.

Tickling elicits vocalizations resembling laughter in non-human species suggesting that it may have evolutionary significance (Panksepp,

2000; Provine 2004). The similarities in play behaviors which elicit laughter from both humans and other great apes provide persuasive evidence of the evolutionary origins of laughter (Weisfeld et al. 2011; Van Hooff 1972). Van Hooff (1972) observed that when non-human primates are engaging in play, they produce a specific facial expression with a relaxed open mouth along with distinctive vocal sounds. Chimpanzees, for instance, may make a guttural repetitive panting sound when they are playing (Ruch and Ekman 2001). Van Hooff (1972) suggested that these vocal sounds may be very adaptive; if two individuals are engaged in boisterous play cooperative vocal sounds will reinforce the playful nature of the situation and will make it clear that there is no real threat even when the relaxed open mouth cannot be easily seen. This play behavior may even be a signal for the play to continue and could potentially have more positive repercussions on the socialization and group relations of chimpanzees who engage in this behavior (Vettin and Todt 2005). Observational research with wild chimpanzees reveals the benefits of social play as Shimada and Sueur (2014) found that more time spent in social play for infant and juvenile chimpanzees was positively associated with having more affiliative social relationships. The adaptive significance of friendships has been shown in humans and non-human animals whereby more social connections confer important fitness benefits (House et al 1988; Seyfarth and Cheney 2012); if humor and laughter help to maintain social connections, it could potentially be argued that they could have been the product of natural selection.

This evidence is not limited to chimpanzees as acoustic analysis suggests that all great apes can “laugh” (Davila Ross et al. 2009). Davila Ross et al. (2009) performed acoustic, then phylogenetic, analyses on vocalizations made by great apes (chimpanzees, gorillas, orangutans, and bonobos) when they were being tickled. The results of this analysis suggested that the differences between human laughter and laughter sounds emitted by other great apes appear to have been shaped within existing variations along the evolutionary line. In other words, the more related humans are to each of the great apes,

the more similar their vocalizations are. Therefore, the vocalizations which occur during play for all species of great ape can indeed be referred to as laughter. This analysis of laughter is particularly important in providing biological support for Provine’s (2004) assertion that the voiced laughter of humans, and later talking, only became a possibility for humans once our ancestors became bipedal. This is an important argument in explaining why our sense of humor evolved beyond tickling and play fighting.

Provine (2004) has proposed that the quadrupedal motion of human ancestors would always have created a restraint on the vocal cords preventing vocalizations; a restraint which could potentially have been alleviated by bipedal motion. Furthermore, if the change to bipedal motion allowed for reduced energy expenditure, a species may have been able to coordinate their breathing which could lead to the development of controlled vocalizations. In turn, this adaptation may have allowed humans to develop egressive (out breath) laughter, in contrast to the ingressive laughter which other great apes demonstrate (Davila Ross et al. 2009). Interestingly, recent evidence has suggested that the laughter of babies is more ingressive and becomes more egressive as we age and start to gain more control over our vocalizations (Sauter et al. 2018), adding support to Provine’s (2004) argument. While laughing can evidently be phylogenetically traced back for 16 million years (Davila Ross et al. 2009), language is likely to be a much more recent phenomenon that may have developed around 200 KYA (Dunbar 2009), although it remains unknown when verbal humor may have begun. Dunbar (2009) has proposed that humor itself may have facilitated the evolution of language because it would have made language more enjoyable, implying that perhaps the evolution of humor may have occurred soon after the first vocalizations.

Verbal Humor

Darwin was the first to suggest that there were parallels between humans and animals in terms of

play behavior such that non-human primates may tickle each other but humans use humor to tickle each other's minds (Darwin 1872/1998). Indeed, as humans age tickling or play fighting becomes inappropriate for adults to engage in (Provine 2004) which may help us to understand the movement away from physical events toward verbal communication. Tickling may not be the only behavior which helps us to understand this process; Barrett et al. (2002) proposed that humorous conversation in humans could serve a similar function to grooming in non-human animals. Grooming is a social activity which is said to aid in bonding and maintaining close relationships (Massen and Koski 2014) in non-human animals. Humans do not groom each other but using humor to induce laughter may be an analogous behavior to grooming (Yip and Martin 2006) and may even provide further benefits as humor use can occur in larger social groups than grooming would (Dezecache and Dunbar 2012; Storey 2002). This is supported by observations carried out by Decache and Dunbar (2012) where they found that laughter tended to be shared between groups of up to four people at once in bars. As such, this may demonstrate that humor is even more useful in creating and maintaining social bonds compared to grooming, play fighting, or tickling (Decache and Dunbar 2012; Dunbar 2012).

The adaptiveness of using humor and laughter in groups is also the subject of a further theory described as the "false-alarm theory" (Ramachandran 1998). Ramachandran (1998) has proposed that laughter may have evolved as a signal to a group that there are no real threats in situations that may cause alarm. It may therefore serve as a way of easing tensions and reinforcing cooperation (Ramachandran 1998). Meyer further elaborates on this theory suggesting that humor and laughter could be used as relief from tension (Meyer 2000). This rings true in situations which could potentially be awkward, for instance when public speakers begin a speech with a joke to "break the ice" (Meyer 2000). Both theories emphasize the nature of humor and laughter as forms of social communication, which again serve to improve relations within a group. Further, acoustic analysis of different laughter types

demonstrates that affiliative, or spontaneous, laughter between friends is easily distinguished from laughter between strangers, as more affiliative laughter tended to be slightly higher pitched and more "sped up" than volitional laughter (Bryant and Aktipis 2014). Bryant et al. (2016) demonstrated that this difference is audible across 24 different societies, suggesting that the distinctive nature of laughter types could be a universal indicator of relationship quality.

This argument is critical to understanding the nature of the evolution of humor; while the sense of humor and laughter appear to be universal, this does not necessarily mean that humor will be *used* or *appreciated* universally. Rather, evidence would suggest that humor is used and appreciated in a discriminating and strategic way to affiliate with specific individuals or groups, a pattern we see throughout the lifespan and in different forms. For instance, there are patterns in humor appreciation which demonstrate cultural differences; Kazarian and Martin (2004) found that Lebanese participants used the same humor styles as Canadian and Belgian participants but significantly differed in the way they used humor, with Lebanese participants using less affiliative humor than both Belgian and Canadian participants. These findings were in-line with cultural predictions in the Lebanese sample, such that participants who identified with more a horizontal collectivistic perspective (associated with maintaining more harmony among group relations) had a stronger preference for affiliative humor whereas a more competitive outlook, vertical individualism, was associated with a stronger preference for aggressive humor (Kazarian and Martin 2004). Later, Kalliny et al. (2006) found cultural differences in humor use when they compared the preferred humor styles of American and Arab participants. These results found that Americans used relatively more self-defeating and self-enhancing humor, supporting the hypotheses made that American individualistic culture would use these humor styles more (Kalliny et al. 2006).

Interestingly, both questionnaire studies not only demonstrated cultural differences in humor use but sex differences too; particularly showing that men tended to use humor more often than

women (Kalliny et al. 2006; Kazarian and Martin 2004). This is particularly true in a mating context where men tend to produce humor and women tend to appreciate humor (Bressler and Balshine 2006; Bressler et al. 2006). Men who are funny are considered to be more attractive and have more mating success (Greengross and Miller 2011), suggesting that a good sense of humor may also be sexually selected.

Humor may also be used to select allies, as well as mates. Experimental research has demonstrated that men have a tendency to be choosy about whose jokes they find funniest, particularly demonstrating that they enjoy the humor of men who are similar to them in dominance (Cowan et al. 2016). As discussed above, creating alliances and friendships with others is highly adaptive (House et al 1988; Seyfarth and Cheney 2012) and both humans and non-human primates demonstrate a preference for creating and maintaining bonds with individuals who are similar to them, known as homophily (Massen and Koski 2014). If humor can be used as a way of finding like-minded individuals, it suggests that it may also be a form of covert signaling which could further strengthen social ties (Smaldino et al. 2018). Covert signaling refers to communicating a message that is clearly understood by some but may not be fully understood by all. Smaldino et al. (2018) suggest that humor could be one way of carrying out covert signaling that could generate cooperative relationships. This parallels the argument put forward by Li et al. (2009) suggesting that humor is used in order to indicate interest to another person, in other words; if an individual expends the cognitive effort of producing humor, it suggests a potential interest in a relationship with the recipient. If the recipient is interested in the speaker, they would typically laugh to indicate that the feeling may be mutual.

Taken together, this evidence may suggest that humor is learned behavior which would weaken the argument that it has evolved. However, it remains likely that humor is a behavior that has evolved and is innate, despite the cultural differences we might see. From birth, infants demonstrate a strong preference for laughing at humorous behaviors their mothers carry out;

MacDonald and Silverman (1978) observed that babies between 10 and 13 months old laughed relatively frequently when their mothers played “peek-a-boo” with them but tended to respond with neutral or wary expressions when strangers did the same. An alternative explanation for this effect could be that infants of this age rely on social cues from their parents to indicate when something is funny and it is therefore not innate. In an effort to test whether perception and appreciation of humorous material was derived from social cues and laughter modeled by parents, Mireault et al. (2015) tested infants’ reactions to absurd and neutral behaviors. Infants were observed while their parents either smiled or laughed at the behaviors (which were being carried out by a researcher), or remained neutral. The results demonstrated that social cues from parents laughing at the absurd events did increase laughter and smiling from the infants; however, there were still observations of laughter and smiling from the infants where their parents remained neutral in affect. Coupled with the observation that infants can smile from 5 to 8 weeks old, and can spontaneously laugh from 3 months of age (Sroufe and Wunsh 1972), the evidence seems to suggest that there exists an innate potential for a sense of humor which may then be reinforced by interaction with caregivers, and shaped by our culture.

Conclusion

It is clear that the sense of humor has previously presented something of an evolutionary conundrum. It is risky, complex, and difficult to produce humor yet it does not appear to have an immediate survival benefit, implying that it may not have been selected for. However, the research discussed above on tickling and laughter in our closet relatives provides compelling evidence that humor does have strong evolutionary foundations. Humor can be used strategically to bond with certain people; in infancy, mothers and babies bond with humor, while later in the lifespan humor can be used to indicate that we favor another person as an ally or a mate. This evidence suggests that humor performs a critical task of

helping individuals to initiate contact and bond with people who are similar to them. As such, perhaps the evolutionary conundrum can be considered somewhat solved as the sense of humor may have aided the development of useful alliances which have contributed toward our survival.

Definition

Definitions of intelligence in the scientific literature center around the idea that that intelligence refers to cognitive processes that allow humans and other animals to solve novel problems in their environments. Thus, Jerison (1973, pp. 16–17) notes that “Although experts differ with regard to the nature of human intelligence, a more or less common ground is that it is a dimension of cognitive behavior – the way one knows the world and the way one uses that knowledge when adapting to changing conditions.”

Introduction

However, intelligence is not the only set of mechanisms designed to enable organisms to cope with environmental novelty. Intelligence is usually distinguished from learning which subsumes a variety of mechanisms that allow the organism to take advantage of temporary regularities in its environment – paradigmatically classical and operant conditioning (MacDonald 2013). Social learning is also usually distinguished from intelligence. Unlike classical and operant conditioning, social learning is not dependent on environmental regularities but on being able to learn by observing how the behavior of others enables the achievement of goals (MacDonald 2013). Organisms capable of social learning are then able to use this information to achieve the same or similar goals.

Intelligence, on the other hand, assumes no environmental regularities (although see discussion of Barrett and Kurzban (2006) below) – even temporary ones – nor does it refer to learning how to achieve a goal by observing others who have already solved the problem. Rather, as stated in Jerison's definition, there is the implication that the organism has a goal and is integrating its knowledge in order to solve problems.

For example, New Caledonian crows are able to quickly process causal information and use it to solve novel problems utilizing new tool types (dropping stones into water in order to gain access to buoyant food items) that are not utilized in their natural environments and have no relationship to their established behavioral repertoire (Taylor et al. 2011). These results do not appear explicable by the use of associative learning, nor is the causal rule linked to regularities utilized by the crows in their EEA. Nor is it the result of having observed other animals or humans successfully solve the problem. Rather, the behavior indicates an ability to develop and utilize an abstract causal rule in order to solve an affective goal – assuaging hunger – by novel means.

Review

Evolution of Intelligence: Theories

There are several theories for why human intelligence evolved, including climate change, the challenges of foraging, and the need to compete with and cooperate with other humans.

Climatic Selection

Vrba (1995) focuses on the finding that harsher ecological conditions (lower temperatures during the early Pleistocene period [2.5–2.8 million ybp]) resulted in higher encephalization quotient (the ratio between actual brain mass and predicted brain mass for an animal of a given size), theorized to be due to the benefits of increased cognitive ability for survival under harsher conditions. Encephalization quotient increased rapidly after this period as well, particularly in the last 500,000–1,000,000 years.

Lynn (2006) proposes that, based on contemporary worldwide IQ patterns, confronting colder, harsher climates resulted in selection for increased cognitive ability. Unlike equatorial Africa, in more northerly climates, humans had to provide means of warmth, and plant foods were only seasonally available, with the result that hunting animals and means of storing food were required. Lynn points to studies indicating an association between latitude and brain size; for example, mean winter temperatures at the present time and during the Würm glaciation are correlated with brain size (which is correlated approximately 0.24 with IQ, with northeast Asia having the lowest mean temperatures and the highest contemporary IQ).

Variability Selection

Related to the climate hypothesis is the theory that humans and other mammals were forced to adapt to inconsistent selection pressures because of rapidly changing ecological conditions – what Potts (1998) terms “variability selection.” Environmental fluctuations became increasingly extreme from the Miocene to the present. These shifts (e.g., between dense, moist forests, and cold, dry

steppe) were unpredictable and nonrepetitive rather than cyclic and included decade-scale fluctuations between glacial and warm conditions and century-long shifts between cold steppe and warm forested conditions, interspersed with periods of climatic stability. Rapid local change also resulted from volcanoes, earthquakes, and tectonic activity.

These climatic shifts are associated with increased diversity of encephalization among mammalian lineages, with some lineages – prototypically the lineage leading to humans – evolving toward larger brains and increased behavioral flexibility. There was a broad trend during the Pleistocene toward the evolution of mammalian taxa that were more flexible in eating habits, patterns of social grouping, and group size in relation to resource availability. “Hominids became less inclined to track particular habitats as change occurred and more capable of adjusting to novel conditions and the increasing range of [climatic] oscillation” (Potts 1998, p. 93).

Across mammalian species, and particularly in the line leading to humans, there are associations among brain size, mental ability, learning ability, flexibility of response, and developmental plasticity. There are also associations among these variables and the elaboration of costly parenting practices, delayed sexual maturation, and a prolonged juvenile period in which social learning is of great importance (e.g., Jerison 1973).

Associations between brain size and innovation have been found among both mammals and birds. Reader and Laland (2002) found an association between executive brain ratio (neocortex and striatum volume over brainstem) and innovation, tool use, and social learning. Their results suggested that there was selection among primates for “adaptive complex variable strategies, such as inventing new behavior, social learning, or using tools” (p. 4440). Social learning frequency was independent of group size, providing support for ecological (foraging) hypotheses for brain evolution in primates.

Harsh and varied climates dovetail with ecological models of increased hominid cranial

capacity, since ecological models posit increased ability to extract resources from the environment, posited by climate theorists to make greater demands in harsh and varied climates. Thus Kaplan et al. (2000) show that humans in traditional societies are adept at extracting resources. However, extracting resources would always be beneficial, independent of harshness of environment, so the ecological theory cannot explain the findings summarized above regarding the association between latitude and brain size and between brain size and highly variable environments.

Ecological Dominance

Several theorists have pointed to social competition among humans as a factor (Alexander 1989; Geary 2015). The essential idea is that once humans established ecological dominance, perhaps as a result of being able to maximize resource extraction as proposed by ecological and climate theories, the main source of selection was competition with other humans.

[T]he ecological dominance of evolving humans diminished the effects of ‘extrinsic’ forces of natural selection such that within-species competition became the principle ‘hostile force of nature’ guiding the long-term evolution of behavioral capacities, traits, and tendencies. (Alexander 1989, p. 458)

As populations get larger due to increased ability to extract resources, there are boom and bust cycles, such as described originally by Malthus, and different human groups come into contact with other groups. These forces create competition among humans. As Geary (2015, p. 109) notes, “the inverse relation between social status, resource control, and mortality risk creates a never-ending cycle whereby Darwin’s and Wallace’s . . . conceptualization of natural selection as a ‘struggle for existence’ becomes in addition a *struggle with other human beings for control* of the resources that support life and allow one to reproduce.” These theorists point to associations among fertility, mortality, and resource control in traditional human societies.

Finally and as elaborated below, it should be noted that confronting novel problems and

opportunities is evolutionarily ancient and that animals have developed a variety of means of solving these challenges, prototypically learning mechanisms capable of taking advantage of ephemeral regularities. Theories of climate change, efficiency at resource extraction, and social competition should be seen as forces that likely selected for greater intelligence in particular species at particular times. However, being able to solve novel problems, being able to take advantage of novel opportunities, and being able to solve ancient evolutionary challenges in a more efficient manner would always be advantageous for any organism. Intelligence would thus be beneficial in any environment. As a result, the theories of the evolution of intelligence discussed above should be seen as proposals about the forces resulting in greater selection pressures for intelligence but that the evolution of intelligence per se need not depend on climate changes, resource extraction, or social competition. As indicated below, there is evidence for a general factor of intelligence in a wide range of mammals and birds, indicating that intelligence evolved many times in many different lineages.

Slow Life History Selection

Another model of the evolution of intelligence posits that it is a consequence of selection favoring slow (high-K) life history strategies. Life history describes the ways in which species trade bioenergetic resources between different domains in order to optimize fitness given variable degrees of environmental harshness and predictability (Ellis et al. 2009). Fast or r-selected life histories are characterized by high investment into mating coupled with diminished investment into offspring care. r-selected species are typically short-lived and tend to be small in size (i.e., rabbits). Slow life history or K-selected life histories by contrast are characterized by high levels of parenting effort coupled with the production of relatively fewer offspring, which will typically attain larger body masses and will live longer (i.e., elephants). Brain mass is positively correlated with indicators of K-selection across mammalian taxa, suggesting that higher intelligence is part of a suite of high-somatic effort behavioral

adaptations in which insight, planning, and behavioral control would be favored, as in harsh, unpredictable environments, thus dovetailing with research on latitude and intelligence cited above (Rushton 2004). Within the lineage leading up to modern humans, dietary shifts, specifically increases in the efficiency with which homins were able to extract resources, may have been a major factor driving the slowing of hominin life history speed, as evidenced both by the increase in encephalization and also longevity characteristic of the more advanced hominins (Kaplan et al. 2000). Among populations of modern humans, it has been suggested that the patterns that exist among group-level variation in intelligence, brain size, longevity, fertility, impulsivity, and prosociality among other traits may have resulted from selection having favored those with slower life history traits (i.e., greater intelligence, brain size, and prosociality coupled with lower fertility and impulsivity), who were better able to anticipate and take advantage of seasonal variability (i.e., predictability) in resource availability, via stockpiling, etc. in more northerly and easterly regions of the globe (Rushton 2004).

Modular Views of Intelligence

From its origins, evolutionary psychology has taken a strong stance on how the minds of animals and humans were constructed, proposing that the minds of animals and humans consist predominantly of highly specialized mechanisms designed to solve specific problems – the massive modularity hypothesis (Tooby and Cosmides 1992). The specific problems that the human mind is designed to solve are those that repeatedly confronted our ancestors over evolutionary time. When organisms are repeatedly confronted by challenges or opportunities, the optimum response is to develop specialized methods of dealing with them. The basic logic of evolutionary psychology is that when the environment presents long-standing problems and recurrent cues relevant to solving them, the best solution is to evolve domain-specific mechanisms, or *modules*, specialized to handle specific inputs and generate particular solutions (Geary 2005).

Applied to intelligence, several theorists have attempted to develop a modular theory of

intelligence. A key issue for a modular view is to account for the available data indicating that humans and animals are able to solve novel problems. The difficulty is that modules must necessarily be activated by particular content domains for which they are specifically designed:

Advocates of evolutionary views do not deny that humans learn, reason, develop, or acquire a culture; however, they do argue that these functions are accomplished at least in part through the operation of cognitive mechanisms that are content-specialized – mechanisms that are activated by particular content domains and that are designed to process information from those domains. (Tooby and Cosmides 1992, p. 166)

Barrett and Kurzban (2006) attempt to retain a modular perspective on intelligence by interpreting domains as referring to the formatting requirements that are required by the brain in order to process the information: “Domains should be construed in terms of the formal properties of information that render it processable by some computational procedure. In this sense, even the rules of so-called content-independent logics – for example, *modus ponens* – are domain specific, in that *modus ponens* operates only on propositional representations of a particular form” (Barrett and Kurzban 2006, p. 634). Defining domains in terms of formatting requirements avoids proposing that mechanisms like working memory are restricted to particular content domains that would be used to solve specific adaptive problems, as proposed by Tooby and Cosmides (1992). Thus, for example, working memory, which is commonly viewed as a component of general intelligence, would be considered modular because the input to working memory must be encoded in a specialized manner, but there is no implication that the contents of working memory are specialized to solve particular problems encountered over evolutionary time.

Within this formulation, modules related to intelligence were thus not designed by natural selection to solve specific problems repeatedly encountered by the organism over evolutionary time. Mechanisms such as *modus ponens* and working memory are not designed to solve any particular problem; rather, they may be used to

solve a very wide and undefined range of problems – solving mathematical problems, making analogies, or figuring out the most efficient way to manufacture pianos. Such processes necessarily conform to a modular view because, while they do not require specific inputs to solve specific adaptive problems, they have specific formatting requirements for the information that they act upon.

The modular view of Barrett and Kurzban (2006) retains the concept that adaptations for intelligence must have evolved in response to environmental regularity. This reflects traditional definitions of adaptations in general. For example, Tooby and Cosmides (1992, 61–62) define adaptation as follows:

An adaptation is (1) a system of inherited and reliably developing properties that recurs among members of a species that (2) became incorporated into the species’ standard design because during the period of their incorporation, (3) they were coordinated with a set of statistically recurrent structural properties outside the adaptation (within in the environment or in other parts of the organism), (4) in such a way that the causal interaction of the two (in the context of the rest of the properties of the organism) produced functional outcomes. . . (Tooby and Cosmides 1992, pp. 61–62; emphasis added)

It is only those conditions that recur, statistically accumulating across many generations, that lead to the construction of complex adaptations . . . For this reason, a major part of adaptationist analysis involves sifting for these environmental or organismic regularities or invariances. (Tooby and Cosmides 1992, p. 69; emphasis added)

Recurrences are thus essential to the construction of adaptations, but this presents a problem for understanding how novel problems can be solved since, by definition, novel problems are not recurrent. Barrett and Kurzban (2012) attempt to analyze the adaptations underlying intelligence and ability to solve novel problems while retaining the idea that adaptations necessarily require recurrences:

Here, we think, there is a definitional issue: at a certain level, the terms “design” and “novelty” are incompatible with each other, because adaptation is impossible without *some* environmental signal, even if statistical and fuzzy, to adapt to. If “novel” means “bears no resemblance to anything in the past,” then design to deal with novelty is a priori

impossible. . . . To be clear, we don't think adaptations designed for novelty are impossible, but only if we redefine "novelty" so as to not make adaptation to it impossible. (Barrett and Kurzban 2012, p. 686; emphasis added)

Thus, according to Barrett and Kurzban (2012), adaptation to novelty would be impossible without recurrences to adapt to. They show that some adaptations may respond to novelty as a by-product of past selection. Novel tokens of types that recurred over evolutionary time are a paradigmatic example. For example, a novel food item (say genetically modified food or a novel creation of a chef) would be processed by the digestive system because it has enough similarity to the sorts of food for which the digestive system was designed. Similarly, a novel three-dimensional object will be processed in an appropriately functional manner by the visual system because the novel item does not depart substantially from the regularities that resulted in the evolution of the visual system.

There is wide agreement among both modular and domain-general theorists that there are specialized content spheres with specific formatting requirements that are component processes in intelligence. These mechanisms are conceptualized as responsive to particular types of recurrent information with specific formatting requirements. As noted, Barrett and Kurzban emphasize the formatting requirements of the inputs to working memory. The model of intelligence proposed by Case et al. (2001) includes specialized, domain-specific content areas (quantitative/relational, spatial/imaginal, verbal/propositional, qualitative/analytic, and causal/experimental) that feed into the executive processing that is central to working memory. An example would be the specialized language centers that process verbal input and produce output into conscious awareness and working memory; this output is thus accessible to executive processing. Geary (2005; see Fig. 1) proposes a variety of highly specialized, domain-specific mechanisms (spatial, verbal, visual object recognition, face recognition, auditory, olfactory, kinesthetic, and gustatory) whose highly specialized, appropriately formatted

outputs feed into and may be acted on by the executive processes of working memory.

Cosmides and Tooby (2000, 2002) proposed a quite different modular theory of novel problem solving, proposing to account for the ability of humans to solve novel problems by the evolution of metarepresentational abilities. For example, they propose a "scope syntax" (Cosmides and Tooby 2002, p. 182) that marks some information as only locally true or false. This syntax includes "a set of procedures, operators, relationships, and data-handling formats that regulate the migration of information among subcomponents of the human cognitive architecture" (Cosmides and Tooby 2002, p. 183). Of particular importance are metarepresentations that allow us to decouple representations of locally true information from the rest of our knowledge base (e.g., John believes that X, where X may be true or false). This allows people to explore the properties of situations, in order to identify sequences of improvised behaviors that may lead to novel, successful outcomes.

This theory of Cosmides and Tooby implies that intelligence involves what one might term "hyper-contextualization" because it highlights local contingencies and an unspecified set of mechanisms that allow for solutions of localized problems in ways not coupled to the modular mechanisms designed to solve evolutionarily recurrent problems. As noted below, this emphasis on hyper-contextualization is quite different than data gathered by intelligence researchers showing that general intelligence facilitates solving novel problems not by emphasizing local contingency but by decontextualization and abstraction.

A Motivational Theory for the Evolution of Domain-General Mechanisms

The first question that a domain-general theory of intelligence must confront is to conceptualize how domain-general mechanisms could evolve. As noted above, a standard account of evolutionary adaptations is that they must respond to environmental conditions that were recurrent over evolutionary time and that adaptations cannot evolve in the absence of such cues. Environmental regularities effectively frame a problem to be solved and

Evolution of Intelligence, The, Fig. 1 An illustration of the proposed relationship between the central executive and a partial list of inputs: auditory, spatial, visual, gustatory, kinesthetic, and olfactory. The central executive directs attention to particular domains (e.g., spatial),

resulting in a conscious representation of the information from that domain. At Time 1 there is no specific focus of attention, but at Time 2, attention is focused on a face, resulting in conscious awareness of the face (From Fig. 7.1 of Geary 2005)

enable the evolution of mechanisms able to respond to the regularity. Regularities provide a built-in sense of relevance – a built-in sense of what the problem is, thus solving what is often termed the “frame problem” in cognitive science. Input stemming from an environmental regularity is automatically framed by the relevant modules because they are designed to be attuned to a particular environmental regularity.

An important aspect of evolution has been to solve the frame problem in a manner that does not rely on environmental regularities for the evolution of psychological adaptations (MacDonald 2013; see also Chiappe and MacDonald 2005). Humans and other animals have evolved motivational systems that solve the frame problem with systems that provide signals when their evolved goals are being met. For example, temperature regulation systems provide signals to seek means of attaining warmer or cooler environments. How

a person or animal solves this problem is unspecified and does not depend on environmental regularities over evolutionary time. However, the temperature-regulating mechanisms effectively frame the problem: They yield information regarding the nature of the problem (i.e., the feeling of being too cold or too warm), and they yield information when the problem has been solved (i.e., attaining a more comfortable temperature). This signal is not a response to an environmental regularity, but rather signals that an internal goal has or has not been met; further, achievement of this internal goal must have been linked to reproductive success in the EEA; but there is no need for reproductive success to be linked to any environmental regularity. As described in the following, such a system enables the evolution of mechanisms able to take advantage of ephemeral environmental regularities (classical and operant conditioning) or imitate successful others (social

learning). Ultimately, via the elaboration of the domain-general mechanisms of general intelligence, affectively grounded systems enable organisms to solve novel problems and (more commonly) to solve ancient evolutionary problems by novel means – means that are more efficient than any possible architecture that is linked to environmental regularities.

From this perspective, a watershed event in evolutionary history was the evolution of subjective psychological signals – positive or negative feelings – that inform the animal when its goals of survival and reproduction are being met or unmet. Imagine a primitive organism equipped only with “if p , then q ” devices, where p represents recurrent environmental events and q represents an evolved response to the event: If a certain environmental situation p occurs (e.g., presence of food), then respond with behavior q (eating). Such an organism would completely satisfy the requirements for a psychological adaptation as described above. The mind is constructed with mechanisms designed to respond adaptively to recurrent environmental events (the presence of p 's). The mechanism is entirely modular, designed to deal exclusively with a particular kind of input (domain-relevant information) by encoding the input in a manner that can be processed by the animal's nervous system; and it produces a particular kind of output (e.g., behavior such as eating p), thereby solving a very specific problem. Its disadvantage would be that there would be no way to take advantage of nonrecurring information in order to find food, for example, the information that a certain ephemerally available stimulus is a cue for food (classical conditioning), the chance discovery that a certain behavior is a good way to obtain food (operant conditioning), or observing another animal successfully obtaining food (social learning).

Examples of “if p , then q ” systems are the modular systems that figure prominently in accounts of general intelligence, such as those enumerated by Geary (2005) (spatial, verbal, visual object recognition, face recognition, auditory, olfactory, kinesthetic, and gustatory). Nevertheless, despite having specific formatting requirements, the information processed by

human modular language systems can be produced voluntarily (i.e., via executive processes) and can be coupled, via learning, to an endless variety of social functions that are not dependent on environmental recurrences. This contrasts with the fixed signaling systems of nonhuman primates and other animals in which signals occur in particular recurrent contexts (e.g., threat, danger, alarm, greeting) and are coupled to the specific circumstances surrounding their use and the functions they serve. Their meaning is therefore fixed. However, the contextual freedom characteristic of humans means that the functions of signals can change quickly over time, making them ideal for dealing with uncertain, novel situations. As in the case of social learning (MacDonald 2013), there is undoubtedly a great deal of specialized neural machinery underlying human language ability. However, like social learning, it functions as a domain-general system, with no evolutionarily fixed inputs or outputs and no fixed relationship to particular environmental regularities. Even infants 3–6 months of age are capable of many-to-many mappings between signal and function; there are a wide variety of signals, many with no social function at all.

Because of the evolution of motivational systems with an affective (reward/punishment) component, a person seeking a warmer or cooler temperature may indeed be confronted with an infinite number of behavioral choices, but the person can narrow down this infinite array by choosing behaviors likely to change the subjective feeling of warmth or coldness. The behaviors that solve the problem may include behavior resulting from ephemeral associations between a previous behavior and reward (classical or operant conditioning) and behavior learned by observing others (social learning), or it may include a mental model that is a part of the evolved machinery of intelligence (developing highly technical plans for building an air conditioner or heating system by taking advantage of knowledge of materials and thermodynamics and making a plan based on imagining possible outcomes – thus relying on mechanisms of general intelligence).

The point is that this affective motive and the fact that certain behaviors reliably result in getting

warmer or cooler give structure to the person's behavior and enable an adaptive choice from among the infinite number of possible behaviors. The resulting behavior is not random because it is motivated by the desire to attain a comfortable temperature. Motivational mechanisms can thus be thought of as a set of adaptive problems to be solved but whose solution is underspecified. Such systems enable the evolution of any cognitive mechanism, no matter how opportunistic, flexible, or domain-general, that is able to solve the problem. None of these ways of solving the problem need to have resulted in solutions that were successful in our evolutionary past.

This fits well with research showing that problem solving is opportunistic: People satisfy their goals, including evolved goals such as satisfying hunger or regulating body temperature, by using any and all available mechanisms. For example, children typically experiment with a variety of strategies and then select the ones that are effective. Children are *bricoleurs*, tinkerers who constantly experiment with a wide range of processes to find solutions to problems as they occur.

These results point to two conclusions: Given that domain generality is evolvable if the animal is equipped with reward-/punishment-type motivational systems, it is not surprising that it is evolutionarily ancient. Indeed, even primitive animals like *Aplysia* (sea slug) possessing very rudimentary nervous systems have associative mechanisms geared to produce adaptive behavior in novel ephemeral environments by pairing a stimulus with a painful unconditioned stimulus (Carew et al. 1981); the conditioned stimulus is limited only by what the nervous system of *Aplysia* can detect and need not be an evolutionarily recurrent stimulus. Secondly, given the rarity of forms of intelligence approaching the human level and even the rarity of sophisticated learning mechanisms, such as social learning, in nature, one must assume that the cost-benefit calculus for elaborating the mechanisms of intelligence and social learning is difficult to overcome. *Aplysia* is doing just fine without the elaboration of these mechanisms.

As described in section “[Evolution of Intelligence: Theories](#),” there has been considerable

debate on what evolutionary pressures resulted in human general intelligence: rapid climactic change, ecological maximization, social competition, or some combination of these. However, given the pervasiveness of domain-general mechanisms in nature and their ancient pedigree, the evolution of intelligence in a sense that would apply to the behavior of New Caledonian crows, rats, humans, and other primates would always be a theoretical possibility. That is, there is no theoretical reason why a very wide range of animals, certainly including birds and mammals, could not have evolved social learning mechanisms or the ability to infer a causal rule from their experience or to visualize and evaluate various hypothetical scenarios in order to satisfy an evolved motive such as hunger or temperature regulation. The affective basis of domain generality is evolutionarily ancient, resulting primitively in simple associative learning mechanisms (classical and operant conditioning), then elaborated greatly with social learning, and finally general intelligence as a suite of mechanisms, particularly the executive processes of working memory (see below) underlying the ability to manipulate information from a variety of sources in order to achieve goals that may or may not be linked with affective motivational systems derived from the evolutionary past.

Although intelligence is usually conceptualized in terms of the ability to solve novel problems, it should also be noted that human general intelligence is adept at finding novel, more efficient ways to solve evolutionarily ancient problems of survival and reproduction (e.g., finding better ways to extract resources from the environment or developing more effective military tactics). The novelty is quite often in the solution, not in the problem itself. Nevertheless, novel problems, as would be presented, for example, in rapidly changing novel environments, certainly pull strongly for intelligence because solutions for these novel problems are necessary for survival.

Research on Animal Intelligence

As noted above, research on New Caledonian crows has established the existence of problem-solving mechanisms able to produce novel

solutions to the ancient evolutionary problem of procuring food. Earlier research by Heinrich (2000) demonstrated the ability of ravens to solve novel problems by using long pieces of string to hang meat from a perch. For ravens, gaining access to this food was a novel problem because it did not occur in their natural environments. The solution involved repeated pulls on the string with the beak while holding and releasing the string with a foot. Though each step in the solution may be innate (e.g., grabbing objects with their beaks or with their feet), assembling these behaviors into a sequence that solves the problem was novel. Not all birds arrived at this solution, indicating individual differences in performance, as there are for general intelligence in humans. The solution did not emerge through a trial-and-error process via learning.

Importantly for conceptualizing the mechanisms underlying intelligence, Heinrich argued that the ravens formulated a goal, built mental models, and evaluated possible sequences of actions without having to endure their consequences. They took into account information from various sources in planning the solution – an obvious drawback to trial-and-error learning. Thus, the ravens did not pull up the string if the piece of meat appeared to be too large, nor did they pull up the string if it was attached to rocks rather than meat. Insightful problem solving involving goals, mental models, and evaluation of possible outcomes has also been demonstrated in apes.

Based on models of human intelligence showing the existence of a *g* factor of general intelligence, several studies have found a general intelligence factor in a wide range of animal species, including a variety of primate species (see Fernandes et al. 2014; Reader et al. 2011), rats, rodents, rabbits, cats, dogs, raccoons, ravens, and pigeons (Galsworthy et al. 2014). Further, tasks that are more *g* loaded are more heritable and are more associated with differences between species and, among humans, among different human groups (reviewed in Fernandes et al. 2014). Using principal axis factoring, Fernandes et al. found that the *g* factor explained 62% of the variance in five cognitive abilities for primates, while, utilizing a different technique, Reader et al. (2011) found a

general factor that explained 65% of the variance across diverse cognitive tasks (behavioral innovation, social learning, tool use, extractive foraging, and tactical deception) using data from 62 primate species. Better performance on these tasks was correlated with brain volume. Reader et al. conclude that their results do not support the massive modularity hypothesis and that social intelligence (e.g., tactical deception) is linked to the general factor of intelligence. Fernandes et al. and Reader et al. both found the highest interspecies variation and loadings associated with tool use, while Woodley of Menie et al. (2015) found that tool use was linked to high interspecies variation, high *g* loadings, and both additive genetic and phenotypic variance. Tool use is hypothesized to be critical for cognitive control of the environment – that is, species and individuals with higher *g* are better able to solve novel problems confronted in their environments. Woodley of Menie et al. concludes that results thus far across a wide range of species support the view that “the *g*-nexus should generalize to all taxa for which *g* is a central component of cognition, indicating profound homology” (p. 162).

A study by Crinella and Yu (1995) suggests that modular mechanisms can be meaningfully linked to a general intelligence factor in animals. They extracted a *g* factor in rats that was based on five tests and accounted for 34% of the variance, a finding that was comparable to studies of *g* in humans (Jensen 1998). Solving these problems typically involved combining information from multiple sources, including from modules specialized for processing spatial information. Spatial learning is a modular process in rats, but the frontal cortex uses the information generated by spatial modules to solve novel problems. The frontal cortex is essential to combining information from different experiences but is not essential to spatial learning per se. The ability to integrate this information with other experiences (e.g., learned associations) is part of a positive manifold linked to success in solving other novel problems and to brain size. As indicated below, models of human intelligence involve combining information from modular mechanisms, such as spatial information, into solutions to novel problems.

Intelligence and Explicit Problem Solving in Humans

The animal data fit well with research on humans, which has consistently found that more intelligent people are better at attaining goals in situations of minimal prior knowledge. Of particular importance is fluid intelligence, defined as “reasoning abilities [consisting] of strategies, heuristics, and automatized systems that must be used in dealing with ‘novel’ problems, educing relations, and solving inductive, deductive, and conjunctive reasoning tasks” (Horn and Hofer 1992, p. 88). Tests of fluid intelligence correlate strongly with *g* (e.g., Carpenter et al. 1990). Tests such as Raven’s Progressive Matrices and Cattell’s Culture Fair Test tap the capacity “to adapt one’s thinking to a new cognitive problem” (Carpenter et al. p. 404). This highlights the idea that intelligence taps conscious problem solving in situations in which past recurrences, including recurrences over evolutionary time, would be unhelpful, except perhaps by analogy or by induction, to the new situation.

Theories proposing a critical role for domain-general processes in intelligence emphasize two fundamentally different processing mechanisms, implicit and explicit processing. Implicit and explicit mechanisms may be contrasted on a number of dimensions (e.g., Geary 2005; MacDonald 2008; Stanovich 2004). Implicit processing is automatic, effortless, and relatively fast and involves parallel processing of large amounts of information. Implicit processing is characteristic of what Stanovich (2004) terms the autonomous set of systems, which respond automatically to domain-relevant information. For example, the visual systems of monkeys and humans contain

numerous areas specialized for different aspects of vision. Areas specialized for color and for motion are sensitive to different aspects of visual stimulation; processing in these different areas occurs in parallel and results in a unitary image. Other modules proposed in the cognitive literature include modules for social exchange, theory of mind, fear, folk physics, and grammar acquisition.

Although implicit processing is characteristic of evolved modules, it is not restricted to evolved modules. It occurs in a wide range of circumstances, including skills and appraisals that have become automatic with practice or repetition, perceptual interpretations of behavior (e.g., stereotypes), and priming effects. Modules, as defined here, therefore need not be domain specific; they may also result from domain-general processes of associative and implicit learning (Stanovich 2004, p. 39) (Table 1).

On the other hand, explicit processing characteristic of intelligent problem solving is conscious, controllable, effortful, and relatively slow and involves serial processing of relatively small amounts of information. Such processing is characteristic of what Stanovich (2004) terms the analytic system characterized by context-free mechanisms of logical thought, planning, and cognitive control. The analytic system is sensitive to linguistic input that allows for explicit representations of the context, including hypothetical representations of the possible consequences of actions. Explicit processing is typically experienced as an internal linguistic monologue that is associated with the experience of agency or free will. The executive processes of working memory are paradigmatic examples of explicit processing.

Evolution of Intelligence, The, Table 1 Characteristics of implicit and explicit cognitive systems

Implicit system	Explicit system
Not reflectively conscious	Conscious
Automatic	Controllable
Fast	Relatively slow
Evolved early	Evolved late
Parallel processing	Sequential processing
High capacity	Limited by attentional and working memory resources
Effortless	Effortful
Evolutionary adaptation or acquired by practice	Acquisition by culture and formal tuition

As an example of explicit processing, consider the Tower of Hanoi problem in which participants must develop a long-term plan with multiple subgoals. This problem requires one to be able to activate multiple goals and keep track of the satisfaction of each of the goals in working memory (Carpenter et al. 1990, p. 413). These goals must be consciously and explicitly held in mind while performing the task. Contrast this type of problem solving with examples of implicit processing, such as everyday perception in which, when we look around the room, our brains are automatically carrying out a large number of operations involving many different specialized modules (e.g., mechanisms for perceiving vertical contours, horizontal contours, motion, color, etc.) that allow us to see the objects in the room. The calculations are done very rapidly, and we are not conscious of making them. This latter situation would not count as an example of intelligent problem solving.

Mechanisms Underlying General Intelligence

As noted, intelligence involves explicit processing. In particular, intelligence involves central executive processes that focus attention on explicit representations of relevant information in working memory while simultaneously inhibiting information not relevant to the problem. Theories of the mechanisms underlying intelligence posit a central executive capable of explicit processing that receives input from a variety of systems, many of them modular mechanisms characterized by implicit processing, including auditory, visual, spatial, or episodic information (i.e., information from life events involving memories derived from a variety of systems) (Baddeley 2000).

Working memory capacity has been implicated as an underlying source of individual differences in fluid intelligence as indicated by moderate to strong correlations between fluid intelligence and working memory capacity (e.g., Kyllonen and Christal 1990). Thus Kyllonen and Christal found correlations from 0.80 to 0.90 between working memory capacity (assessed by tasks such as digit span and mental arithmetic) and reasoning ability (assessed by performance on

analogies and verbal reasoning). Engle et al. showed that the executive functions of working memory (assessed by tasks involving attentional control) predicted *g*, but that short-term memory capacity (assessed by tasks such as memory for sets of words) did not.

Individual differences in working memory capacity reflect differences in the capacity for controlled attention, including the ability to inhibit irrelevant information. Kane et al. (2001) found that participants with low working memory capacity were less able to inhibit the prepotent response of orienting toward a visual cue in a task that required them to look in the direction opposite the cue (looking toward a visual cue is an automatic response; looking away from a visual cue requires suppression of an automatic response; see MacDonald 2008). This supports the idea that working memory capacity plays a crucial role in controlling attention in situations in which responding does not involve automatic implicit processing – that is, in situations requiring active engagement with task goals and the inhibition of prepotent, automatic responses.

As noted above, goal management is an important feature of animal intelligence. One role of the executive functions in solving novel problems is to manage goals. This involves constructing, executing, and maintaining a mental plan of action during the solution of a novel problem (Carpenter et al. 1990). For example, the Raven's Progressive Matrices fluid intelligence test and the Tower of Hanoi problem (in which participants must develop a long-term plan with multiple subgoals) both require one to be able to activate a goal with multiple subgoals and keep track of the satisfaction of each of the subgoals (Carpenter et al. p. 413).

Executive functions underlying general intelligence are thus involved when problems call for substantial planning and keeping track of various subgoals. They are involved in dealing with situations that are highly demanding of attentional resources, as more aspects of the problem require attention. More complex tasks require more involvement of controlled processes that structure and analyze the problem, assemble a strategy of attack on it, monitor the performance process, and

adapt these strategies as performance proceeds. Keeping task-relevant information in active state is particularly challenging in conditions in which distracting information is present (Kane et al. 2001).

Is Working Memory a Domain-General Mechanism?

The executive functions of working memory and the mechanisms of activation and inhibition do not satisfy the criteria for modularity. By definition, mechanisms for solving novel problems have to be unspecialized in the domains for which they provide solutions. Although they may have access to specialized information obtained from the various modules that provide them with inputs, the problem-solving procedures would have to be general enough to allow the solution of novel problems in various domains. For example, there is a substantial correlation between performance on the Raven's Progressive Matrices and performance on the Tower of Hanoi puzzle (Carpenter et al. 1990). Both tasks require goal management, working memory, and inhibition of prepotent responses. However, the types of information used in solving these problems, the specific goals and subgoals, and the specific responses requiring suppression are unique to each task, and the tasks themselves are not problems that were recurrent in the EEA.

Moreover, measures of working memory capacity predict performance across a wide range of tasks. The only common element of these tasks is that they make high demands on attentional resources, indicating that a general capacity is involved. For example, people who did well on a mathematical processing task also tended to do well on a perceptual task requiring inhibition of prepotent responses (Kane et al. 2001). This is what one would expect if working memory "reflects an abiding, domain-free capability that is independent of any one processing task" (Kane et al. 2001, p. 169).

The executive functions are thus able to access goal-relevant information from a wide range of domains when solving a problem. Indeed, it is in being able to access representations from more

modular processes that the executive functions are able to extend cognitive competencies in ways that are unrelated to their evolutionary function. The data on general intelligence in animals is also consistent with this view. For example, Thompson et al. (1990) found that six brain regions were involved in psychometric *g* for the rat, including a visuospatial attentional mechanism, a visual discrimination mechanism, a vestibular-proprioceptive-kinesthetic discrimination mechanism, a place learning mechanism, and a nonspecific mechanism. This is consistent with models of human intelligence (Case et al. 2001).

There is much evidence that general intelligence facilitates the integration of information obtained from modules. Geary's (2005) distinction between biologically primary and biologically secondary abilities is useful in this regard. Biologically primary abilities are domain specific and include abilities such as language and simple quantitative abilities, which develop universally and spontaneously. Biologically secondary abilities, such as reading and mathematical ability, use these domain-specific modules, but in a novel manner. Rather than seeming to be spontaneous and effortless, biologically secondary abilities typically require practice and tuition, often with coercion, bribery, or exhortation. Learning these biologically secondary abilities involves explicit, conscious awareness rather than implicit awareness. Success at these biologically secondary abilities is strongly correlated with general intelligence (Geary 2005).

As a case in point, human language results from highly dedicated systems that enable children to effortlessly and unconsciously learn extraordinarily complex grammatical rules. However, skill in integrating these language systems as well as the output of visual processing mechanisms into an evolutionarily novel ability – reading – is strongly linked to general intelligence. Unlike language learning, reading is typically mastered only with a great deal of conscious effort and represents a major hurdle for many schoolchildren. The correlation between IQ and reading skills ranges from about 0.6 to 0.7, even longitudinally (e.g., Stevenson et al. 1976). IQ

correlates with reading most when decoding ability – a specialized, likely modular process – is controlled (Jensen 1998). Children at the third- or fourth-grade level are adept at decoding, and individual differences are mainly in comprehension. Reading comprehension is approximately as highly correlated with verbal as with nonverbal IQ.

Decontextualization as a Function of General Intelligence

Decontextualization enables humans to inhibit the operation of highly context-sensitive, implicit, and automatic heuristics for making inferences, judgments, and decisions (Stanovich 2004). Decontextualization enables dealing with novel and unpredictable environments because a common source of solutions to novel problems involves recognizing similarities between new problems and previously solved problems, as via analogical reasoning (Chiappe and MacDonald 2005).

As noted, logical thought, planning, and cognitive control are fundamental to intelligence, and since they operate in a context-free manner (Stanovich 2004), they are not tied to recurrent contexts but operate to find general rules, as in the example of the New Caledonian crows noted above. IQ researchers are well aware of the centrality of decontextualization for thinking about intelligence.

One of the well-known byproducts of schooling is an increased ability to decontextualize problems. In almost every subject... pupils learn to discover the general rule that applies to a highly specific situation and to apply a general rule in a wide variety of different contexts. The use of symbols to stand for things in reading (and musical notation); basic arithmetic operations; consistencies in spelling, grammar, and punctuation; regularities and generalizations in history; categorizing, serializing, enumerating, and inferring in science, and so on. Learning to do these things, which are all part of the school curriculum, instills cognitive habits that can be called decontextualization of cognitive skills. The tasks seen in many nonverbal or culture-reduced tests call for no scholastic knowledge *per se*, but do call for the ability to decontextualize novel situations by discovering rules or regularities and then using them to solve the problem. (Jensen 1998, p. 325).

Conclusion

As noted above, there is excellent evidence that general intelligence is an adaptation underlying the ability of humans to solve problems where subjects have a minimal amount of prior knowledge. Such problems are novel because they have not been previously encountered by the subject, and thus it is not surprising that more intelligent people are able to create novel solutions to ancient problems of survival and reproduction (Chiappe and MacDonald 2005). Research on human intelligence has shown that the degree to which the *g* factor loads onto cognitive ability measures positively moderates the association between these measures and a variety of biological variables, including brain size, reaction time, and inbreeding-depression effects, and also with phenotypic and genetic characteristics associated with performance on the tests, such as the magnitude of population differences in cognitive performance (Jensen 1998; Rushton and Jensen 2010). This demonstrates that it is the most domain-general measures of intelligence that have the highest validity in predicting biologically meaningful manifestations of cognition. Furthermore, the most domain-general measures of intelligence enjoy the highest criterion validity – meaning that they are better at measuring the real-world advantages that stem from high IQ (Rushton and Jensen 2010). Such individuals tend to make more money, perform better in scholastic and workplace environments, and achieve a higher social status than people on the low end of the IQ distribution. They are also more conscious of personal health and safety. On the job, the *g* factor is the best single predictor of job performance. Correlations between *g* and job performance range between 0.2 and 0.8, with greater predictive validity achieved for jobs of greater complexity. Thus, people with higher general intelligence are more adept at attaining their evolutionary goals in situations of novelty, complexity, and unpredictability – consistent with the hypothesized functions of *g* as a psychological adaptation designed by selection (Chiappe and MacDonald 2005; Geary 2005).

General intelligence is therefore at the heart of an evolutionary analysis. Although modules designed to process specific types of information are unquestionably important to an evolutionary analysis, evolutionary psychology has over-emphasized modularity and ignored the vast data indicating a prominent role for domain-general mechanisms in human and animal cognition. Indeed, research has uncovered associations between a general intelligence factor and ability to solve problems that have often been advanced as solved by domain-specific modules, such as cheater detection, social exchange, and learning (Chiappe and MacDonald 2005; Fernandes et al. 2014). Fernandes et al. also point out that very similar cognitive abilities have been found in widely divergent species (e.g., various primate species and hyenas) despite very different ecologies. The prediction from massive modularity theory – that the principal source of species differences in intelligence should be unique because each species has its own set of specialized modules that evolved to solve species-specific problems – is not supported.

Domain-general mechanisms are powerful but fallible mechanisms that are the basis for solving a fundamental problem faced by all but the simplest organisms: the problem of navigating constantly changing environments presenting new challenges that have not been recurrent problems in the EEA. Most important, the domain-general mechanisms at the heart of human cognition are responsible for the decontextualization and abstraction processes critical to the scientific and technological advances that virtually define civilization (Chiappe and MacDonald 2005).

Evolution of Live Birth in Mammals (140 MYA)

Ashley Rankin and Nikki Clauss
Oklahoma State University, Stillwater, OK, USA

Synonyms

Genomic imprinting; Gestation; Lactation; Viviparity

Definition

Bringing forth live young that have developed inside the maternal body, usually via the placenta.

Introduction

Mammals have extended maternal investment either through gestation or lactation, which may

explain how mammals can develop more robust brains (Tutin and Collins 1981). There are two infraclasses in mammals that are viviparous (i.e., giving birth to live young), marsupials and placentals (also known as eutherian mammals). Placental mammals diverged from marsupials roughly 140 MYA. This split resulted in a number of changes including reproductive anatomy and the length of the gestation and lactation periods. Placentals typically have an extended gestation period through which the embryo receives its nutrients through the placenta. Marsupials on the other hand usually have an extended lactation period in which the underdeveloped fetus receives the majority of its nutrients through its mother's milk.

Overview

There are two infraclasses in mammals that are viviparous (i.e., giving birth to live young), marsupials and placentals. The combination of viviparity, placentation, and lactation has made mammalian reproduction extremely successful (Renfree et al. 2013). Placental mammals diverged from marsupials roughly 140 MYA. However, there is new evidence to suggest this split may have occurred earlier (Luo et al. 2011). In both marsupial and placental mammals, females invest heavily in reproduction compared to males. Both marsupials and placentals have extended maternal investment compared to non-mammalian species either through gestation or lactation (Tutin and Collins 1981). Placentals typically have an extended gestation period through which the embryo receives its nutrients through the placenta. Marsupials on the other hand typically have an extended lactation period in which the underdeveloped fetus receives the majority of its nutrients through its mother's milk. There are a number of hypotheses that attempt at explaining the evolution of mammalian reproduction: conflict hypothesis, coadaptation hypothesis, and an explanation through life history.

The conflict hypothesis (also known as the Kinship hypothesis) is the most widely accepted and empirically supported hypothesis to date. This hypothesis assumes that the degree of

asymmetries will arise when the female breeds with multiple males (i.e., offspring may have the same mother, but different fathers; Ashbrook and Hager 2013). The conflict hypothesis also assumes the cost of gene expression is heavier for either the mother or father. The conflict hypothesis proposes that paternal genes enhance fetal growth while maternal genes suppress it.

This hypothesis is supported by the findings that several of the imprinted genes that increase growth are usually paternally expressed (e.g., *Igf2*) and the maternally expressed genes usually restrict growth (e.g., *Phlda2*; Renfree et al. 2013). Although maternal-offspring conflict is used to explain genomic imprinting, Trivers (1974) suggests this also can explain a conflict in behaviors. For example, during the weaning stage of lactation, the costs to the mother (e.g., lactation) begin to outweigh the benefits to the offspring since the offspring can find its own food. Therefore, the mother may begin to restrict the offspring's access to milk as the offspring finds its own food.

The coadaptation hypothesis assumes that the mother is the primary caregiver and the genotype of the offspring will affect interactions with the mother (Ashbrook and Hager 2013). This hypothesis also assumes that the genes that control the maternal phenotype may also effect the offspring's phenotype. The coadaptation hypothesis proposes that coadaptation between the mother and offspring is what is driving genomic imprinting. This hypothesis is supported by the findings that paternally expressed genes (e.g., *Peg3*) may also be involved in maternal care, placental nurturing, and regulation of attachment to the nipple and sucking behavior (Renfree et al. 2013).

Another explanation is that life history evolution effects placental morphology, which has been demonstrated in nonmammalian species (Fisher et al. 2001). Compared to faster life histories, slow-paced life histories are characterized by longer gestation periods, longer maximum lifespans, less offspring per female, longer generation times, older first reproduction, older onset of senescence, and slower senescence. Therefore, when there is an increase in the availability of resources and a decrease in environmentally driven mortality, a slower life history may be favored.

Reproductive Anatomy

The anatomy of the female reproductive tract differs between marsupials and placental mammals. In most marsupials, there are two vaginae, two cervixes, two uteri, and two fallopian tubes compared to most placentals which has one vagina, one cervix, one uterus, and two fallopian tubes (Tyndale-Biscoe and Renfree 1987). Marsupials have paired lateral vaginae that connect to their corresponding uteri to form the vaginal culs de sac. From the vaginal culs de sac, twin uterine cervixes open and are connected to the uterus of the same side (Taggart 1994). The uterine neck that connects the cervixes to the uteri varies in length depending on the species. During parturition, the two vaginae form a temporary median vagina (i.e., birth canal) that connects to the urogenital sinus. Since most placentals only have one vagina, one cervix, one uterus, and two fallopian tubes, the two fallopian tubes connect to the uterus. The uterus then connects to the cervix and the cervix connects to the vagina. The anatomy of the placenta will be discussed later.

Gestation Period

Gestation is a period in which a developing fetus is inside the womb and completely dependent of its mother. Compared to marsupial gestation which rarely exceeds 1 month and can be as short as 12 days, placental gestation can take much longer ranging 2 weeks to 2 years (Fisher et al. 2001; Langer 2008). This longer gestation period in placentals allows for a more mature neonatal brain compared to that of marsupials with similar brain sizes (Smith 1997). Shorter gestation in marsupials allows for the mother to jettison a pregnancy or young if conditions become extremely harsh.

Placentae

During the gestation period, the mammalian young are nourished via the placenta. The evolution of placenta has long been debated. Although it was once attempted to classify animals via the placenta, because it is one of the most varied

organ in the mammalian class, this is no longer the case. The placenta varies on invasiveness and size, but in all cases the fetus cannot survive without it.

In placental mammals, the placenta is a temporary organ that joins the mother and fetus, transferring oxygen and nutrients from the mother to the fetus and transferring waste away from the fetus. The placenta is characterized by five major features: (i) the definitive type of placental interface, (ii) fetomaternal interdigitation, (iii) placental shape, (iv) fetomaternal blood flow interrelations, and (v) neonatal/placental weight ratio (Wildman et al. 2006). The definitive type of placental interface is likely to have had at least 11 character state changes occurring since its original evolution. The placental shape is likely to have had seven character state changes since its original evolution, with primate placental shapes changing within its order (Wildman et al. 2006).

Compared to its placental counterpart, marsupials have received much less research on its yolk sac placenta, which evolution continues to be debated (Freyer et al. 2003). One of the major differences in placentals and marsupials in regards to the embryo is the lack of an inner cell mass in the blastocyst (Renfree 2010). The yolk sac contains two parts: a bilaminar, nonvascular region and a trilaminar vascular part. In addition to the yolk sac, marsupials have a permeable “shell” coat that is eventually broken down and lost.

In placental mammals, the placenta plays a role in the release of hormones that are found normally in the body (e.g., prolactin). The placenta may also augment the functions of hormones from other sources (e.g., chorionic somatomammotropin) which act as supplementary hormones to stimulate gonadal, mammary, adrenal, and thyroid functions. Although it has been understudied compared to the placental placenta, marsupial placentae also play a role in hormones. For example, in the tammar wallaby, the placenta plays a role in cortisol, growth hormones, and relaxin (Renfree 2010).

Genomic Imprinting

One of the major features of the gestation period in mammals is genomic imprinting. Imprinted

genes are genes that are expressed in a parent-of-origin-specific manner. Imprinted genes play a role in various aspects of placental and fetal development including fetal and placental growth, neonatal behavior and lethality, postnatal lethality, growth, and viability (Coan et al. 2005). This suggests that imprinting may have been vital to the evolution of the placenta. The number of genes imprinted varies between species; for example, mice have more imprinted genes than humans.

One gene in particular, *Igf2*, is imprinted in all placental and marsupial species that have been studied. This suggests that *Igf2* evolved before placentals diverged from marsupials and after milk production evolved. Therefore, one possible explanation is imprinted genes evolved due to greater maternal investment. However, there has been mixed findings with imprinting of *Igf2* in nonmammalian species.

Lactation Period

Once the mother gives birth, the lactation period begins. One of the key features that define the mammalian class is its milk production. Although nonmammalian animals produce milk (e.g., flamingos, penguins, etc.), it is not analogous to the complex nutrient transfer via a modification of the maternal physiology (Renfree et al. 2013). Milk has a variety of benefits including rich macro- and micronutrient and several health-promoting roles and is primarily composed of three parts: protein-rich whey, casein micelles, and milk fat globule (Khaldi et al. 2014; Jensen 2002).

Two antimicrobial enzymes xanthine oxidoreductase (XOR) and lysozyme may be why milk has high immunological and nutritional values (Shahani et al. 1973). It was originally hypothesized that the nutritional value of milk evolved subsequently to its immunological function (Hayssen and Blackburn 1985). New evidence supports this notion, but suggests that the immunological response may have evolved subsequently to its nutritional role (Vorbach et al. 2006). Vorbach et al. (2006) describes how

mammary glands evolved from mucus surface epithelia and muscle skin glands, which secreted only antimicrobial enzymes like the ones mentioned above. Then, muscle skin glands evolved into lactating mammary glands which had a protective (i.e., produced antimicrobial enzymes) and nutritional role (i.e., produced fat droplets, α -lactalbumin, and lactose).

Lactation in placentals can be broken up into two phases, milk-only and mixed feeding, when the mother is weaning the young off. The timing of lactation varies from species to species. As mentioned above, life history traits may affect this timing of lactation, although recent evidence suggests that this is not the case. Langer (2008) found that there was neither a relationship between life history traits and milk solids nor adult food quality in a number of mammalian orders. This may give evidence for the coadaptation hypothesis discussed above.

Although placentals and marsupials both produce milk that is protective and nutritional, marsupials have a more complex, extended lactation period (Tyndale-Biscoe and Renfree 1987). For both placentals and marsupials, the mammary gland produces milk via a positive feedback loop in response to the sucking stimulus. As mentioned above, the neonatal marsupial brain is less developed compared to a placental brain (Smith 1997). This is because the majority of marsupial maternal investment focuses on lactation. Marsupial lactation lasts up to 20 times longer than the gestation period (Fisher et al. 2001). Once the underdeveloped offspring is born, it crawls into its mothers pouch and feeds until it can transition into exclusively solid food.

Marsupials not only produce milk, but can simultaneously produce milk of different nutritional composition. For example, the tamar wallaby has four nipples and four phases of lactation. In phase 1, all four mammary glands prepare for lactation during pregnancy. In phase 2, the underdeveloped offspring climbs into the pouch and attaches to the teat of one of the mammary glands. During phase 2, the teat the offspring is attached to continues to lactate, while the other three regress. Milk during this phase has low levels of fat and protein with elevated levels of

carbohydrates. In phase 3, the offspring begins to exit the pouch to eat grass and while continuing to suck, but less often. Milk during this phase has an increase of protein and fat and a decrease of carbohydrate and overall gross milk production. At phase 4, the offspring leaves the pouch permanently, but continues to suck until fully weaned (Trott et al. 2003). Additionally, tammar wallabies can have two different-aged offspring nursing off of two different nipples that secrete milk with compositions suitable for which phase they are in (Brennan et al. 2007).

Conclusion

The combination of viviparity, placentation, and lactation has made mammalian reproduction extremely successful (Renfree et al. 2013). There are two infraclasses in mammals that are viviparous (i.e., giving birth to live young), marsupials and placentals. Placental mammals diverged from marsupials roughly 140 MYA. There are a number of hypotheses that attempt at explaining the evolution of mammalian reproduction: conflict hypothesis, coadaptation hypothesis, and an explanation through life history. In both marsupial and placental mammals, females invest heavily in reproduction compared to males. Both marsupials and placentals have extended maternal investment either through gestation or lactation (Tutin and Collins 1981). Placentals typically have an extended gestation period through which the embryo received the majority of its nutrients through the placenta. Marsupials on the other hand usually have an extended lactation period in which the underdeveloped fetus receives the majority of its nutrients through its mother's milk.

Evolution of Long-Term Pair-Bonding in Humans

Kelly Rooker and Sergey Gavrilets
University of Tennessee, Knoxville, TN, USA

Synonyms

Evolution of mating systems; Human evolution; Social monogamy

Definition

Long-term pair-bonding occurs when one breeding male and one breeding female share a common territory, associating with each other for more than just one breeding season regardless of whether or not they currently have any offspring together. In humans, long-term pair-bonding can occur via monogamous or polygamous relationships.

Introduction

Humans have previously been called the “uniquely unique species” (Alexander 1990). Despite there being many different factors contributing to this uniqueness (e.g., the large brain),

one of the most important is humans having a multi-male, multi-female social organization and a long-term pair-bonding mating system (Flinn et al. 2005; Geary and Flinn 2001; Hill et al. 2011). Most species living in groups composed of multiple males and multiple females are promiscuous, while most pair-bonded species live in groups comprised of only one male and one female. There are no primates other than humans where multiple reproductive pairs live together (de Waal and Gavrilets 2013). Nuclear and extended families, as well as parental investment in offspring, are characteristics found in all human societies (Geary and Flinn 2001); such characteristics clearly set humans apart from their African ape ancestors (de Waal and Gavrilets 2013; Flinn et al. 2005). The question then is how could humans have evolved such a unique combination of social organization and mating system.

In fact, long-term pair-bonding in humans has always been considered an evolutionary mystery. Why is this practice so common in human societies around the world? How did long-term pair-bonding first evolve in humans? What were the evolutionary pressures making it beneficial to humans? Although these questions have all been asked repeatedly for decades, even centuries, there has yet to be any real consensus on their answers. Still, much progress has been made.

Monogamy and pair-bonding often get used interchangeably, but “monogamy” can mean many different things. For instance, *cultural monogamy* refers to human institutions such as marriage. *Sexual monogamy* is in reference only to sexual relations; one male and one female will mate exclusively with one another, but have no or few interactions outside of that sexual intercourse. Similarly, *genetic monogamy* is when all offspring produced by one male or female in that pair have that same mother and father. Rates of genetic monogamy can be tested in the field by looking at the genetic makeup of all offspring produced (Reichard and Boesch 2003).

Finally, there is *social monogamy* or what is more commonly called *pair-bonding*. In social monogamy, one male and one female exclusively assort with each other. This assortment is not just in terms of copulations or the genetics of their

offspring, but also in terms of with whom they live, where they sleep, and most generally where they spend their time (Reichard and Boesch 2003). In other words, under social monogamy, one breeding male and one breeding female will share a common territory, associating with each other for more than just one breeding season, regardless of whether or not they currently have any offspring together (Lukas and Clutton-Brock 2013).

It should be noted that many researchers do not restrict the word “pair-bonding” to involving *only* one male and one female. Rather, the term is often used more broadly to describe any lasting reproductive relations between particular males and females. For example, in polygyny where one male is having such lasting reproductive relations with multiple females, some would say that male is just having multiple distinct pair-bonds occurring simultaneously (Reichard and Boesch 2003). Using this terminology, humans as a whole are very much considered having long-term pair-bonds since every known human society has practiced either polygamy or monogamy (and hence long-term pair-bonding) (Chapais 2008). Considering only the raw number of human societies throughout the world (vs. also the populations of each of these societies), only about 17 % of such societies practice social monogamy. The vast majority of the rest (>80 %) practice polygyny. Even among the polygynous societies though, only a small minority of the men in each are actually polygynous; most males lack sufficient resources needed to support multiple female mates (Reichard and Boesch 2003).

True genetic monogamy is rare in humans, even in the socially monogamous cases (Reichard and Boesch 2003). However, despite the widespread prevalence of extra-pair matings, there still has yet to be a human society with sexual promiscuity as the main form of mating system (Chapais 2008). Hence, for the rest of this entry, “long-term pair-bonding” will be synonymous with “social monogamy,” thus including both monogamy and polygamy. For cases where one male and one female *do* remain exclusive with each other, this entry instead refers to these as *strict monogamy*.

In addition to all these different types of monogamy, the word “monogamy” can also

imply differences in duration. *Long-term monogamy* implies the one male and one female which form a pair will remain together across many breeding seasons. *Life-long monogamy* is then a different term used to describe when a male and female’s long-term monogamy in fact lasts for the rest of their lives. Conversely, *short-term monogamy* refers to monogamy that typically lasts for only one breeding season or year; one male and one female will be monogamous to each other, but only within that limited amount of time. Cases where pairs practice short-term monogamy throughout their lives, but in each instance of short-term monogamy have a different partner, are instead referred to as practicing *serial monogamy* (Reichard and Boesch 2003).

For example, many species of birds will be monogamous throughout each breeding season (or other period of time), but then each individual will have a different mate come next breeding season (Reichard and Boesch 2003). This means such birds are monogamous *within* breeding seasons, but not monogamous *between* breeding seasons (i.e., serial monogamy). In addition, human societies where divorce is common, as well as remarriage for both men and women following divorce, have mating systems resembling serial monogamy (Reichard and Boesch 2003).

Monogamy from a female’s perspective often makes a lot of sense. In eutherian mammal reproduction, only females must go through the costly periods of internal gestation and lactation (Opie et al. 2013). Not only are such activities quite energetically expensive for females, they make predation, death, and other injuries to the female more likely. In addition, due to relatively long gestation and lactation periods, female eutherian mammals are also much more limited than males are in the quantity of offspring they are able to have in a lifetime. While males are limited only in the number of copulations they are able to obtain with fertile females, females have their main constraint as time (Kappeler 2013).

In a monogamous mating system, having a male remain with/around a female could help the female in any number of ways, be it protection of her and/or her offspring/resources, help in securing meat or other valuable resources, and/or help

in caring for any offspring produced from the union. All of these would help loosen the female's main constraint (time) either by allowing a female's interbirth interval to be shortened (e.g., by a male helping with parental care of the older offspring), improving her health which leads to longer times of fertility (e.g., by provisioning the female with valuable foods), and/or lengthening her life and hence her fertile period (e.g., by protecting her from other males or predators) (Kappeler 2013).

On the other hand, of critical importance when considering the evolution of long-term pair-bonding is why *males* would ever play their role in a socially monogamous mating system. In eutherian mammals, males have much greater potential for producing more offspring throughout their lives than females (Kappeler 2013), due to the aforementioned female traits of internal gestation and lactation (Opie et al. 2013). This means that males mating with only one female throughout their lives are sacrificing all that "extra" reproductive potential. Thus, for long-term pair-bonding to evolve, there would have to be some fitness compensation present to make up for that loss in male reproductive potential (Kappeler 2013). The rest of this entry is primarily concerned with considering the many possible forms of such "fitness compensation."

Although certainly not prevalent, long-term pair-bonding is widespread throughout the animal kingdom. Long-term pair-bonding is most notably found in birds and mammals. Among mammals, about 3 % of species practice long-term pair-bonding (Kleiman 1977). Even the newer, upper estimate of 9 % of mammals practicing social monogamy (Lukas and Clutton-Brock 2013) pales in comparison to the 90 % of birds estimated to practice social monogamy. However, these 3–9 % of mammal species are found in many different clades of mammals, and long-term pair-bonding is believed to have evolved independently upward of *sixty* different times in mammals (Lukas and Clutton-Brock 2013).

Such pair-bonding in mammals may appear to be strictly behavioral, but neurophysiology has also been shown to play a role. Certain neuropeptide pathways (e.g., oxytocin, arginine

vasopressin, and prolactin) have been shown to have been co-opted to form pair-bonding reward pathways in several species of monogamous mammals, including primates (Lovejoy 2009). Compared to birds, social and genetic monogamy in mammals are tightly correlated, meaning mammals' rates of extra-pair copulations are relatively low (Lukas and Clutton-Brock 2013).

Rates of long-term pair-bonding of course vary significantly among mammal species. While some mammalian orders contain zero socially monogamous species, about 29 % of primate species are socially monogamous (Lukas and Clutton-Brock 2013). In addition, primates are unique among mammals in that social monogamy has evolved independently in every major primate clade, and there are relatively few transitions away from monogamy once it has evolved (Opie et al. 2013).

Among just anthropoid primates, long-term pair-bonding is believed to have evolved independently seven different times, three in Platyrrhini (New World monkeys) and four in Catarrhini (apes and Old World monkeys). Indeed, socially monogamous species among anthropoid primates today include species as varied as New World monkeys (e.g., marmosets, tamarins), Old World monkeys (e.g., De Brazza's monkeys, Sumatran surilis), and apes (e.g., gibbons, humans) (Sillen-Tullberg and Moller 1993). Despite social monogamy not being ubiquitous among primates, its widespread prevalence indicates there must be some significant benefit to species practicing social monogamy. Although this entry focuses on humans, many of the hypotheses and ideas presented below could similarly apply to many of these other primate species as well.

It is the aim here to first discuss the transition *to* long-term pair-bonding: what were human societies like prior to long-term pair-bonding becoming the norm? Second, the many hypotheses which have been given to explain the evolution of long-term pair-bonding in humans will be discussed. Then, both empirical and theoretical work will be looked at as they pertain to each of these hypotheses. Finally, other work which takes a broader look at the question of long-term pair-bonding in humans will be discussed.

Pathways for the Transition to Monogamy in Groups

Part of the debate surrounding the evolution of long-term pair-bonding in humans is over the ancestral social organization and mating system of genus *Homo*. Were human ancestors monogamous? Or promiscuous? Did they live solitary? In one-male groups? Or in multi-male, multi-female groups? These ancestral-state questions are still very much debated, with many researchers having wildly different, and often directly contradicting, views (Duda and Zrzavy 2013).

Humans, and many other primate species, are group living. Such groups of individuals come in various sizes, but all with their associated benefits and costs (Hill et al. 2011). For instance, groups afford members protection against both predators and other groups. Such protection could come from group members' alarm calling, alerting other group members of some impending danger, or in the form of an alliance against a predator or invading group. Groups can also facilitate resource sharing, whether it be with meat, other valuable foods, or other resources. Individuals in groups are better guaranteed a steady supply of nourishment, with food sharing in groups especially helping with food/resource scarcity in the event of a drought or other severe ecological conditions. In the case of species with alloparenting, group living can help with child-rearing and allowing females to have more offspring than they would be able to otherwise. Finally, group living may also help with acquiring mates. By living in groups with at least one male and one female, potential mates are always nearby and mating attempts likely easier to facilitate (Flinn et al. 2005).

On the other hand, group living can also come with potential costs to all group members, primarily from ecological competition (for resources, mates, etc.) (Hill et al. 2011). Living in groups can result in conflict between group members. Such conflict can be energetically costly to those group members, even resulting in injury or death if fighting is the outcome. Living in close proximity to others can increase theft of resources, food, mates, etc., making group members expend

more energy and time guarding such resources and again potentially fighting over them. Finally, visibility by a predator, disease, and other parasites becomes more prevalent when living in the higher population densities that come with groups. Such risk would be absorbed by all group members, not only potentially resulting in increased susceptibility to predation, lasting disability, and death but also potentially in loss of resources and other vulnerabilities (Flinn et al. 2005).

Humans' closest living relative, the chimpanzee, is certainly a group-living species. Chimpanzees live in highly promiscuous multi-male, multi-female societies. Most evidence does not point to monogamy being the ancestral state of the chimpanzee-human last common ancestor. Rather, their ancestral state was likely some type of promiscuity, with monogamy in humans being a derived trait. However, this broad framework still leaves much room for debate in terms of what that ancestral human social organization, and resulting mating system, specifically looked like (Chapais 2013). The following are the four main pathways which have been proposed for such an ancestral state.

Promiscuity

First, the *Pan*-human last common ancestor could have been very much like *Pan* (chimpanzees and bonobos). In this case, the ancestral state for *Homo* would be individuals living in fully promiscuous (i.e., with no stable mating bonds) multi-male, multi-female groups. From this backdrop, humans would have retained this multi-male, multi-female social organization, but then evolved to a socially monogamous mating system from the promiscuous *Pan*-like one (Chapais 2013).

Harems

An often-favored alternative to the above is if the *Pan*-human last common ancestor had a harem-style mating system, similar to that of gorillas. In this case, the social organization would have consisted of groups made up of one male with many females (his "harem") and then lone roaming males outside of any group. The one

male in the harem would mate with all of the females in the harem and also provide protection/guard them, while the roaming males got few, if any, copulation opportunities. From this backdrop, humans would have reorganized into a social organization consisting of multiple males and multiple females making up any one group while still keeping their long-term pair-bonding structure (Chapais 2013). Evidence for this pathway includes humans' *australopithecine* ancestors having large body size sexual dimorphism (larger than either chimpanzees, modern-day humans, or later human ancestors), which is indicative of fierce one-on-one male competition, as seen in gorillas (Geary and Flinn 2001). In addition, one mathematical modeling approach found this pathway to be the most likely one leading to humans (Nakahashi and Horiuchi 2012).

Multilevel Societies

A third alternative discussed is the idea of multilevel societies. Here, the chimpanzee-human last common ancestor would have lived with a social organization and mating system similar to hamadryas baboons. Under this framework, males still have harems (i.e., groups made up of one male and multiple females, all of whom that one male mates with and protects), but then multiple harems live together in larger groups, often referred to as "clans." Under this backdrop, these larger groups would already be practicing long-term pair-bonding. However, from this humans could have even evolved strict (one-male, one-female) monogamy, since "clans" could contain "harems" of one male and precisely one female. If the size of the male harem was reduced to only female per male, strict monogamy would be the effective result (Chapais 2013).

Strict Monogamy

Finally, although considered unlikely by many, it is also possible that strict monogamy was the ancestral mating system for humans. Similar to gibbons and other primates with such monogamy, monogamous pairs would have been spaced out geographically and not had any kind of group social organization. What evolved from this backdrop would then be the group social organization:

monogamous pairs moving closer to each other, ultimately forming multi-male, multi-female groups while still retaining their monogamous mating system. Again, although this pathway is certainly a logical transition, there is little evidence supporting the chimpanzee-human last common ancestor being strictly monogamous (Chapais 2013; Sillen-Tullberg and Moller 1993).

Hypotheses for the Evolution of Social Monogamy

Regardless of from where exactly it came, there is no doubt that long-term pair-bonding evolved at some point in humans' past. Similar to the debate over the ancestral state of *Homo*, there is also much debate over how long-term pair-bonding first evolved in humans. Again, there have been many different hypotheses proposed, some directly contradicting each other, and relatively little headway made in finding concrete answers as to which hypothesis is the most likely. Despite no consensus after decades of research, progress has still been made. Note some hypotheses presented below are unique to humans, while others are more widely applicable to many primates or even mammals in general. Some hypotheses are also highly dependent on one or more of the pathways discussed above, while other hypotheses could still be possible regardless of the specific pathway from which early humans evolved. Also note that some hypotheses below only work with regard to strict monogamy (these will be noted), while most do not specify the type of long-term pair-bonding needed.

In general, all the hypotheses discussed below can be grouped into four main categories. The first is ecological. This hypothesis has gained much support for the evolution of social monogamy among nonhuman mammals, but is widely discredited as being a factor in the evolution of social monogamy in humans. The second group of hypotheses include those having to do with protection, of either the offspring, the mate, or one's self. The third group of hypotheses relates to food: provisioning of the mate, the offspring, or in cooperation. Finally, the fourth group of

hypotheses involves conflict, either strictly between males fighting over mates, group-related, or among siblings produced by the same male. It should be noted that most of these hypotheses are not mutually exclusive, but rather two or more could have simultaneously contributed selection pressure to the evolution of long-term pair-bonding in humans.

Ecological Hypothesis

The first hypothesis discussed here is the “ecological” hypothesis (Komers and Brotherton 1997). Females are assumed to be solitary and relatively spaced out geographically (due to ecological competition), while males are roaming, looking for mates. However, because of the females’ geographic spacing, it may become increasingly lucrative for a male to stick to just one female’s range. Doing so will save males’ energy resources expended in searching for females and also better guarantee males a mate. If they instead wandered, males would have to travel long distances between females with no guarantee of, first, even finding another female, and, second, her desiring to mate with said male once found (Komers and Brotherton 1997).

A recent study found the most likely ancestral state for all nonhuman mammals is solitary females and roaming males with overlapping ranges (Lukas and Clutton-Brock 2013). They then found social monogamy to have evolved in nonhuman mammals under conditions involving intense female-female competition, low female density, and where breeding females were intolerant of sharing their ranges. Under these conditions, males would likely be unable to defend access to more than one female. Among all nonhuman mammals, socially monogamous species today do in fact live at significantly lower densities than solitary species, even after controlling for body size differences and despite the fact that both socially monogamous and solitary species share similar home-range sizes (Lukas and Clutton-Brock 2013).

Although considered by many to be a favored hypothesis for the evolution of social monogamy in nonhuman mammals, this hypothesis is much less accepted with regard to human evolution since

humans did not likely come from solitary ancestors. Each of the three pathways which assume humans had non-strictly monogamous ancestors (i.e., three of the four discussed above) all centers on early humans living in groups of more than two individuals (Kappeler 2013). However, it is certainly possible that changes in early human dietary patterns (even within groups) lowered female densities, making it much harder for one male to guard multiple females. In this way, a transition from polygyny to strict monogamy could still have been facilitated in humans under the ecological hypothesis (Lukas and Clutton-Brock 2013).

Protection Hypotheses

The following three hypotheses all deal with protection as the main selection pressure on early humans for the evolution of long-term pair-bonding.

The first hypothesis under this category deals with protection of one’s offspring, namely, protecting them against the risk of infanticide. Infanticide, the practice of killing an infant not one’s own prior to it being weaned, has been widely documented across primates (van Schaik and Dunbar 1990). In most instances, infanticide is committed by a new alpha male who has just taken over a group. By killing any infants not his in the group prior to their weaning, he is forcing their mothers to return to fertility sooner, increasing the probability of him having offspring with one or more of those ex-mothers and hence increasing his overall fitness. Such evolutionary benefit for males has already been well-established (van Schaik and Dunbar 1990).

Having an offspring killed in its first year of life is clearly very costly; the biological mother and father would each get zero fitness benefit from the said offspring, despite the mother (and possibly the father as well) investing much time and energy into the pregnancy and early life of the offspring. As such, it may behoove the father to stick around that offspring up until the point it gets weaned in order to protect it from any infanticidal attacks by other males. In doing so, such a male has effectively formed the groundwork for having a pair-bond with the mother of his offspring (van Schaik and Dunbar 1990).

Infanticide is quite common among primates, in large part due to altriciality (and in turn long durations of lactation), which makes the infants more susceptible to having infanticide committed against them (Opie et al. 2013). These facts would hold for humans as well. In addition, Opie et al. found that in primate phylogeny, infanticide by males typically precedes social monogamy (Opie et al. 2013). They concluded that not only is social monogamy in primates much more likely to evolve in the presence of high male infanticide, once social monogamy *does* evolve, it is more likely for there to be a subsequent decline in the amount of male infanticide than an increase in the level of polygyny (Opie et al. 2013).

There is still much debate over the role of infanticide in the evolution of long-term pair-bonding in nonhuman mammals. Contrary to the Opie et al. work discussed above, other prominent researchers (Lukas and Clutton-Brock 2013) found “the available evidence suggests that male infanticide is unlikely to be the principal mechanism for the evolution of social monogamy in mammals.” Despite finding rates of male infanticide among socially monogamous species (9 %) to be lower than rates among solitary species (27 %), they concluded from their analysis that this difference was most likely due to “an independent evolution of the two traits” (Lukas and Clutton-Brock 2013).

One key factor considered there was that in most socially monogamous mammals, the duration of female lactation does not typically exceed her gestation period. However, it is in cases where such lactation duration *does* exceed gestation length that a benefit would be expected for males killing other males’ offspring (Lukas and Clutton-Brock 2013). This is because female mammals will not typically have two unweaned offspring concurrently. Hence, if lactation duration exceeds gestation length, there is benefit to the male in killing one offspring, so the next (his) can be born sooner and the female will still only have one unweaned offspring at any given time (Opie et al. 2013).

For example, in modern-day humans, one study found 50 % of nursing women to return to normal estrous cycling within 10 months of

giving birth and 100 % of the women by 20 months, while the cross-cultural average age of weaning in humans is 30 months (Quinlan 2008). In chimpanzees, offspring are typically weaned around 4 years of age, while females on average only have one offspring every 5 years, meaning female chimpanzees will also only have one offspring to care for at a time (Pillsworth and Haselton 2006).

The second hypothesis under the category of protection deals with mate guarding or a male protecting his mate. In most formulations, this hypothesis centers on the idea of paternity certainty. After mating with a female, males can either stay around that one female (“guarding” her) or leave her in search of new mates. By guarding her, a male can prevent other males from mating with that female (which can increase his fitness by reducing or eliminating completely any sperm competition), as well as offer protection to her physical well-being (discussed later). Roaming males attempting to copulate with a guarded female normally face a high cost-to-benefit ratio in any fight with a male guard, and the guards typically win these fights (Reichard and Boesch 2003).

In general, a male must choose between acquiring *more* mates and increasing his paternity certainty with *one* mate. If conditions make the latter more important to a male’s fitness than the former, one could expect pair-bonding to evolve, as the male constantly remains near his one mate to help ensure paternity certainty, which would increase his fitness (Hawkes 2004). However, note that mathematical models of this hypothesis have not supported mate guarding as a strong enough selection pressure for long-term pair-bonding to evolve (e.g., see Gavrillets (2012)).

Among socially monogamous species, levels of mate guarding vary drastically. Kokko and Morrell (2005) constructed a theoretical model and found that males will evolve to guard little if females are either very faithful or very unfaithful. The intuition behind this finding is again that in gaining paternity, males face a trade-off between having more mates and increasing paternity certainty in their one mate. Hence, if a female is highly faithful, her mate would be able to gain

more mates by guarding little, with little risk to the paternity certainty of his mate's offspring. Similarly if a female is highly unfaithful, her mate would likely have little to lose by trying to gain more mates by guarding little since even if he spent his time/energy instead guarding her, she would likely still sneak copulations outside this mating bond. In addition, Kokko and Morrell found that attractive males are predicted to guard less, with the intuition being they are more likely to find *more* mates, and hence paternity certainty becomes less crucial in the trade-off (Kokko and Morrell 2005).

A related hypothesis to mate guarding, involving the direct physical protection of one's mate mentioned earlier, is the bodyguard hypothesis (Chapais 2008). Rather than paternity certainty being the driving selection force behind the evolution of long-term pair-bonding, it could instead be physical protection of the female. If a group is such that a female must be constantly worried about harassment/violence from other males, her (and her future offspring's) fitness would be increased by having the male stick around her. However, in doing so he would also be increasing his paternity certainty, especially if the harassment she was receiving was sexual in nature, meaning the mate guarding and bodyguard hypotheses are largely indistinguishable (Chapais 2008).

The last hypothesis in this category deals with protection of one's self, namely, against the threat of sexually transmitted diseases (STDs) (Kokko et al. 2002). This hypothesis hinges on the fact that STDs were increasingly problematic among early humans, as group size and population density increased (i.e., as humans became increasingly ecologically dominant). As these STDs became more widespread and lethal, the costs of having sexual relations with multiple partners greatly increased. If such costs increased sufficiently enough, it could have been better in terms of a male's fitness to have *fewer* mates rather than more. If that was the case, individuals would have switched to a strategy favoring remaining faithful to one or two mates rather than promiscuity, and hence long-term pair-bonding could have evolved (Kokko et al. 2002).

In addition, using the same reasoning, STDs could influence female choice. A female may view a dominant male, or a male who has mated with many females, as too risky to mate with due to the threat of getting an STD from him. Hence, females may actively begin rejecting mating with such males. Mathematical models have supported this hypothesis as a way for mating systems to change and long-term pair-bonding to become more prevalent (Kokko et al. 2002).

Provisioning Hypotheses

These next three hypotheses all fall under the category of food or other provisionings as the key selection pressure on the evolution of long-term pair-bonding in early humans.

The first hypothesis under this category, food-for-sex, deals with males provisioning their mates or, in particular, males provisioning females in exchange for copulations. As hunting became more important in early human history, and also the nutrients obtained from meat more valuable, females could increase their fitnesses by mating with males in order to obtain more high-benefit foods or other valuable resources. Females were able to increase their fitnesses through such beneficial provisionings, while males increased their fitnesses by increasing their likelihoods of obtaining mates. Provided such benefits were strong enough, and these exchanges consistently occurring between the same male and female, long-term pair-bonding could ultimately be selected for (Reichard and Boesch 2003).

Such exchanges of important foods for copulations are routinely seen in the genus *Pan* (chimpanzees and bonobos). "Important foods" include meats and fruits high in fats and/or proteins, as well as foods requiring increased search time (Lovejoy 2009). Looking at primates, there is an association between the evolution of social monogamy and a reliance on relatively scarce foods (Lukas and Clutton-Brock 2013). Fruit, compared to foods like gum, bark, and fungi, offers much higher nutritional value while also being a more limited resource. Indeed, fruit constitutes a main part of the diet in about 90 % of socially monogamous primate species and only 28 % of solitary primate species. Conversely,

foods like gum, bark, and fungi constitute the main part of the diet in about 40 % of socially monogamous primate species and 78 % of solitary primate species (Lukas and Clutton-Brock 2013).

In addition, a hypothesis related to both the above and the ecological hypothesis, the resource defense hypothesis, posits that social monogamy could have evolved from a male defending a highly valued (e.g., due to food resources) territory, able to keep all intruders out. In this case, a female may want to remain in that territory permanently, not so much because of the male himself, but because of the valuable territory he is able to control (Reichard and Boesch 2003).

The next hypothesis in this group, paternal care, looks at a different type of male provisioning, this time to his offspring (Benshoof and Thornhill 1979). Parental investment is any expenditure benefiting an individual's offspring at some cost to that individual (even if just an inability to invest that energy into other fitness components) (Quinlan 2008). Offspring fitness is increased when a male is around to help provision the said offspring. Provided this helping male is indeed the offspring's biological father, the male will be helping his own fitness as well (Wittenberger and Tilson 1980). 59 % of socially monogamous mammal species have been found to have regular carrying or provisioning of offspring by males, whereas only *three* non-monogamous mammal species have such carrying or provisioning (Lukas and Clutton-Brock 2013). Mammals in particular may require the extra help from offspring provisioning because of that special energy-intensive (i.e., 670 kcal/day in humans) lactation period in a female mammal's life (Quinlan 2008).

In addition, some researchers believe that as the human brain got bigger and human infants became increasingly dependent on others (altricial) during the early years of their lives, mothers were no longer able to care for their offspring alone (Benshoof and Thornhill 1979). For instance, children cross-culturally consume more calories than they produce until at least age fifteen; contrast this with chimpanzees who typically produce more calories than they consume by age five (Conroy-Beam et al. 2015). Over the past

4 million years, human ancestors underwent a doubling of the length of their developmental period (Geary and Flinn 2001). Among modern-day hunter-gatherers, females on average have one child every 3–4 years, meaning most women will have multiple dependent offspring to care for at the same time, unlike in chimpanzees and other primates (Pillsworth and Haselton 2006). In addition, parental investment in offspring does not just stop; rather, it often continues all the way through to become “grandparental investment” (i.e., alloparenting) (Conroy-Beam et al. 2015).

If more than one adult was needed to care for an offspring, fitness-wise it made sense that that “other adult” would be the offspring's biological father, since no other adult (besides the mother) would have as much genetic material invested in the offspring. As hunting became more important in the early human diet, males (the hunters) were increasingly needed as meat providers. Hence it could have been some combination of increasingly altricial offspring, the importance of hunting, and bipedality (meaning humans were more easily able to carry offspring and/or the provisionings) that could have helped long-term pair-bonding to evolve, provided paternity certainty was sufficiently high (Benshoof and Thornhill 1979). However, two separate phylogenetic analyses suggest that paternal care is more likely to be a secondary adaptation occurring either with or after the evolution of long-term pair-bonding, rather than a main driver of this evolution (Lukas and Clutton-Brock 2013; Opie et al. 2013).

The next hypothesis under this category, related to both parental investment and food-for-sex, is that of economic interdependence (Conroy-Beam et al. 2015). Much research has gone into the evolution of a division of labor among early humans, namely, why, how, and when did men and women become solely responsible for specific and different tasks or chores. The economic interdependence hypothesis hinges on the fact that, on average, men have more strength/endurance needed for hunting large game than women do. In addition, during pregnancy and lactation, women are already expending more energy in their daily lives than men and would likely encounter increased risk during large-game hunts

(Conroy-Beam et al. 2015). For example, a pregnant female requires 8–10 % more in caloric intake than a nonpregnant female and a lactating female about 26 % more (Pillsworth and Haselton 2006).

Under this hypothesis, males and females would then engage in economic partnerships, whereby each sex would focus on that resource acquisition they could accomplish most efficiently. Hence, males would provide meat for a female and her offspring, and the female would share with him the foods she had produced or gathered. Not only does this give females easier access to valuable meat, it also provides males with protection in the event that he is unsuccessful in hunts (Conroy-Beam et al. 2015).

A related idea to this involves the idea of cooking (Wrangham et al. 1999). Cooking food is beneficial in terms of (1) calorie intake, (2) protection from disease or other sickness due to food poisoning, and (3) increasing the edible range of plant foods through digestibility. While men went out to hunt, women were left at the camp and hence became in charge of cooking. While males relied on women then for the cooked food each night they came back to camp, women in turn also relied on the men to help protect these valuable cooked foods as well as any foods which had already been gathered but yet to be cooked. It is in this way that such a relationship benefited both the male and female and could have fostered the formation of long-term pair-bonds (Wrangham et al. 1999).

Once producing one's own food became prevalent among early human societies, there were two main strategies each individual could adopt, producing vs. scrounging. An individual following the producing strategy would be focused on producing his/her own food and then storing such food for later consumption. On the other hand, an individual following the scrounging strategy would instead not be focused on producing his/her own food, but rather finding already-produced food elsewhere. Since females were naturally less mobile (due to the demands and restrictions of pregnancy, lactation, and parental care) and males naturally stronger, a logical division of labor resulted where females followed the producing strategy and males the scrounging strategy.

However, this means males were often stealing already-produced foods from females, making it in females' best interests to "buy protection" in any way they could. Since one such form of payment could be the female giving one male her exclusive reproductive rights, long-term pair-bonds could have evolved under this selection pressure (Wrangham et al. 1999).

Conflict Hypotheses

Finally, this last category of hypotheses all deals with conflict as the main selection pressure for the evolution of long-term pair-bonding in early humans.

The first hypothesis in this category, one specifically relating to humans, has to do with the idea of leveling (Chapais 2013). As tool and weapon use became increasingly common across early humans, male size/strength dimorphism became less important in fights. Just because an alpha male is bigger and stronger than a lower-ranked male does not necessarily give that alpha male an advantage in a physical confrontation if the lower-ranked male has more and/or better tools/weapons available to him than the alpha male (Chapais 2013). This meant that any fights between two now-evenly-matched males were much more costly to both males involved and also more likely to end without a winner despite the larger cost involved. Hence, it was harder and more costly for an alpha male to protect any "harem" of females, making pairs of one male and only one female increasingly common until only strict monogamy was left (Chapais 2008).

Males fighting over mates can be very costly to a group as a whole. If males' time and energy are being spent in intragroup conflict, there will be less time and energy available to devote to intergroup conflict. As such, this second hypothesis under the category of conflict predicts that groups with more monogamous pairs will be more successful in the long term than promiscuous groups which routinely have intragroup fighting over mates. This hypothesis posits that since cooperation is key to early human survival and long-term pair-bonding supports such cooperation, long-term pair-bonding could have been able to evolve (Chapais 2013).

There is little doubt that cooperation is in fact key to early human survival. Humans are a cooperative group-living species, and coalitions are often formed in human social competition (Geary and Flinn 2001). Among contemporary hunter-gatherers, cooperation is shown in ways far exceeding that of other primate species. Such examples include sharing food across all members in the group, groups having high levels of alloparental offspring care, cooperative hunting or other food acquisition strategies, construction and maintenance of living spaces, transportation of children or resources, contribution to public goods, etc. (Hill et al. 2011).

There is some evidence for this hypothesis from the palaeontological record (Lovejoy 2009), albeit rather controversial. Fossils 4.4 million years old of *Ardipithecus ramidus*, a species occurring relatively soon after the hominin/chimpanzee split, indicate reduced sexual size dimorphism and reduced upper canine teeth size, both of which are indicative of a decline in male-male conflict (Lovejoy 2009). *Homo erectus* appeared about 1.5–2 million years ago with males about 20 % heavier than females (similar to the sexual dimorphism seen in today's humans). Contrast this with the 60 % heavier males found in the *Australopithecine* species from up to 5 million years ago (Geary and Flinn 2001). If reduction in intragroup conflict was a driving force behind early human evolution, it would be expected that related characteristics like sexual dimorphism would evolve quickly in humans' ancestral line. The above fossil record provides support for this idea.

One intriguing alternative related to this hypothesis is if long-term pair-bonding evolved via cultural evolution (i.e., as an institution via marriage) instead (Henrich et al. 2012). This means that instead of relying on the evolution of *gene(s)* relating to long-term pair-bonding, it is instead *cultural* traits (norms) that are important in this evolution. Humans and their ancestors are still sexually dimorphic in size (as discussed above), an indication that the species should perhaps not be considered genetically monogamous and that it is culture playing the crucial role instead (de Waal and Gavrillets 2013). However, note these cultural

hypotheses would be operating on a much shorter time scale than the genetic hypotheses (i.e., tens of thousands vs. hundreds of thousands of years) (Fortunato and Archetti 2010).

Henrich et al. question how one-male, one-female (strict) monogamy came to be when approximately 85 % of societies (meaning raw number, not considering each society's population size) in the anthropological record allow for polygyny. They reason that strict monogamy was favored by cultural evolution because of how much it benefits groups (i.e., cultural group selection). Similar to the above *gene* evolution, because of those benefits, groups with strict monogamy would do better in the long term than their counterpart groups with polygamy (Henrich et al. 2012).

So where do such benefits come from? As already discussed, monogamy can lower male-male competition within a group; it can also reduce the number of unmated males within the group. This is true regardless of the mating system of the comparative group (i.e., promiscuous vs. polygynous). Having fewer unmated males within a group can reduce crime rates (for murder, rape, assault, robbery, etc.) and other personal abuses which are harmful to groups. Males low enough in rank/status that they get no mating opportunities will have essentially zero fitness and thus, evolutionarily, nothing to lose. This creates males who are more willing to take risks in order to get copulations and hence creates conflicts within their groups (Henrich et al. 2012). Again, groups who impose long-term pair-bonding as the social order will do better than those that do not. Under this hypothesis, even if selection on the actual genes is not strong enough to produce long-term pair-bonding, such evolution is still possible, just considering instead evolution on the related cultural traits.

Finally, the last hypothesis considered here deals with conflict between a male's various offspring, especially if produced by different females (Fortunato and Archetti 2010). As it became the norm for humans for property and/or other resources to be passed on to the next generation, more clearly defined familial lines became increasingly beneficial. A father's fitness can be decreased by having to split his wealth (resources)

among the more offspring he would have by having more mates. Strict monogamy would allow male/female mating bonds to be stable over time and hence all the male's resources to be given to his offspring, all full siblings. In this way, strict monogamy could simply be a strategic behavior on behalf of males and females in allocating their resources to the next generation (Fortunato and Archetti 2010).

In particular, Fortunato and Archetti (2010) constructed a mathematical model and found two conditions which would make strict monogamy (or "monogamous marriage" in their words) the most beneficial cultural mating system. First is when there is unigeniture, meaning only one offspring inheriting all of a parent's wealth, and second is when women are more faithful in a monogamous bond than a polygynous one. If the latter is the case, while men would still have that fitness loss from not mating with more than one woman, they *would* get a benefit from that one woman being more faithful than otherwise (i.e., increased paternity certainty). Note the female of this long-term pair-bond would also benefit, in that her male mate would be investing his resources exclusively in her children for the next generation (Fortunato and Archetti 2010).

This hypothesis could help explain why monogamous marriage is so common in societies with intensive agriculture (e.g., plow or irrigation agriculture of much of Europe and Asia, as opposed to hoe agriculture or pastoralism of much of sub-Saharan Africa). In intensive agriculture, land is often the limiting resource, so splitting land among multiple heirs can only go so far. Hence, this hypothesis would be predicted to have much greater selective pressure under intensive agriculture than other forms of agriculture (Fortunato and Archetti 2010).

Comparative Work

Most of the research discussed above focuses on only one of these hypotheses. There is relatively little comparative work done pitting such hypotheses against each other. One exception to this is Gavrilets (2012). In this paper, Gavrilets constructed models for several of the above

hypotheses in order to look at how long-term pair-bonding could have evolved in early humans' past. In particular, he found that long-term pair-bonding was rarely predicted to evolve in (1) the baseline scenario ("communal care"; males allocate some amount of effort toward helping *all* offspring in their group), (2) with mate guarding, (3) with food-for-sex, and (4) with "mate provisioning" (equivalent to the food-for-sex hypothesis except males are only able to provision one female and females to be provisioned by one male) (Gavrilets 2012).

However, long-term pair-bonding *was* able to evolve provided two things were present: (1) inequalities between males in their fighting abilities (i.e., rank among males in a group) and (2) differences in females in both "faithfulness" (how faithful any given female will be to her mate) and choosiness (for a male who will provision her more). These results imply that it is likely that more than just mate guarding or food-for-sex is needed in order for long-term pair-bonding to evolve. Not only is male rank important (since lower-ranked males may initially be the only ones who do better pursuing a pair-bonding mating strategy), but females' ability to choose mates (namely, those who provision more and/or provide more care) is also important in allowing long-term pair-bonding to evolve (Gavrilets 2012).

The above study looked at individual fitnesses, meaning how different mating systems could have evolved by benefiting the individuals within such a system (Gavrilets 2012). Another theoretical study instead took a group selection approach, looking at how different mating systems could have evolved by benefiting *groups* as a whole (Nakahashi and Horiuchi 2012). These authors constructed a mathematical model looking at the evolution of the alpha male strategy, as well as female mating and grouping strategies. In particular, they found that a human-type mating system (i.e., one in which groups consist of multiple females and multiple males, male-male competition is weak, and there is no female promiscuity) can evolve when having a larger group is beneficial (e.g., in defense against other groups) and when the cost of female promiscuity is large (e.g., due to the many types of human venereal diseases) (Nakahashi and Horiuchi 2012).

Conclusion

Despite all the research and curiosity surrounding the evolution of long-term pair-bonding in humans, few concrete answers have yet to be obtained. In particular, there is still debate over the ancestral mating system in early humans, as well as the main selection pressure(s) resulting in humans switching their mating system to one of long-term pair-bonding. Indeed, researchers still contradict each other over whether the chimpanzee-human last common ancestor had a promiscuous mating system (like chimpanzees), a harem-style polygynous mating system (like gorillas), or multilevel societies (like hamadryas baboons). Many of the hypotheses for the evolution of long-term pair-bonding in humans have more support under only one of these mating system ancestral states, making this a related, and equally important, research question.

In terms of how long-term pair-bonding evolved and whether strict monogamy was a culturally and/or genetically evolved trait in humans, these are both still very much unanswered research questions. Many different researchers have contributed much to this ever-growing body of literature spanning over a century, but few agreed-upon answers have yet been obtained. Some hypotheses have certainly gained more support throughout the years than others, but there are still so many being actively considered. The time is ripe for researching human origins, and progress will likely be made in this upcoming decade. Being human, it is only natural to ask the question of from where did this species come and to investigate those traits that make humans the “uniquely unique species” (Alexander 1990). The human universal of forming long-term pair-bonds is just one such trait.

Evolution of sight in mammals

Definition

The history of heritable modifications that improved and limited the visual systems of mammals, and their associated sense of sight, over the course of successive generations.

Introduction

Light contains a wealth of sensory information that is critical to many animals' daily lives; from the color of a ripening fruit to gauging the distance to a nearby shelter or spotting the movement of an incoming predator, visual cues play a

foundational role in these organisms' survival. While the eyes of all vertebrates are derived from a common ancestor, they have been adapted to a myriad of different ecological niches. Mammalian visual systems in particular have undergone considerable flux throughout their evolution.

Pre-mammalian Eyes

While there are many different shapes and sizes of eyes across the animal kingdom, vertebrate eyes are typically single-chambered structures described as being "camera-like" with an open aperture in the front directing incoming light onto the photosensitive retina which, in the camera analogy, acts somewhat like the camera's film. When it comes to what sets mammalian vision apart from other vertebrates, however, the shape of the eye is less divergent than the organization and development of the retina and photoreceptors, known as rods and cones. Rods are highly sensitive to light and are responsible for scotopic, or nocturnal, vision. They contain a high concentration of photosensitive pigments, improving each cell's ability to detect individual photons, and the resulting signals are amplified as multiple rods synapse with each ganglion cell (Hauzman et al. 2018). This signal convergence drastically improves sensitivity, at the cost of overall acuity. Cone photoreceptors amplify visual acuity for photopic, or diurnal, vision. Cones are less sensitive to light and are activated in high luminosity conditions; however they allow for the discrimination of different colors, mediated by comparing the outputs of different cone subtypes that each express photopigments tuned to respond maximally to specific wavelengths of light.

Reptiles and birds have evolved four cone opsin types, sensitive to long, medium, short, and ultraviolet wavelengths of light. These opsins can be expressed within one of the two morphologically distinct cone subtypes; single cones, which can produce one opsin type each, or double cones that typically express either the long-wavelength opsin or both the long and medium opsins in tandem (Bowmaker 2008; Enright et al. 2015). Inside these cones is a particularly interesting adaptation: small globules of colored oil

that act as tiny micro-lenses and light filters to help improve color discrimination (Toomey and Corbo 2017). In mammal lineages, however, these vision-enhancing adaptations have largely been lost. Most mammals have only two cone opsin classes (Jacobs 2009), and while some marsupials have retained both the oil droplets and double cones with the long-wavelength opsin (Ahnelt et al. 1995), the loss is complete in Eutherian (placental) mammals, as illustrated in Fig. 1. Instead most mammals have an eye design more optimized for low-light conditions, with higher sensitivity at the cost of lower acuity (Heesy and Hall 2010). It has been proposed that this difference hints towards a period of strong selection towards a nocturnal lifestyle early in the evolution of mammals.

The Nocturnal Bottleneck

During the Mesozoic era, 250 million years ago, reptilian dinosaurs were a dominant force in the world. Ancestral mammals at the time presumably developed strategies for surviving against such formidable predators. A prominent hypothesis is that in order to avoid the large reptiles, who were likely ectothermic and active mostly during the day, most early mammals adopted a nocturnal lifestyle (Walls 1942). This shift in their behavioral niche would have required them to adapt to seeing in low-light conditions, involving significant restructuring of their visual systems. Even after the extinction of the dinosaurs, and the release of the strong pressure to remain nocturnal, mammals have retained many features that hint at their nocturnal ancestry to this day. The overall shape of mammalian eyes tends to favor larger corneal diameters relative to axial length, a feature common in nocturnal birds and lizards (Hall et al. 2012). This eye design allows for more light to enter the eye at once, an adaptation that maximizes sensitivity in low-light conditions at the cost of visual acuity. The ratio of photoreceptors in the retina has also been skewed heavily in favor of the highly sensitive rods (Gerkema et al. 2013; Kim et al. 2016). The source of rod photoreceptors during eye development appears to have expanded in mammals compared to fish,

such that cells that would otherwise produce cones evolved to produce rods, perhaps to accommodate or empower the nocturnal shift in habits of early mammals (Kim et al. 2016).

This trend towards visual sensitivity at all costs is reflected not only in the structural changes to the visual system but also in the mammalian genome. The photopigments that allow for color discrimination are produced by a series of opsin genes. Vertebrates produce one rod opsin (RH1) and four classes of cone opsin genes: two for short-wavelength opsins (SWS1 and SWS2), a long-wavelength opsin (LWS), and a rod-like cone opsin (Rh2) that is tuned to medium wavelengths (Jacobs 2013). While the full complement of cone opsin classes can be found in other vertebrates, no mammal expresses more than two. Mammals managed to preserve the long-wavelength-sensitive opsin, but the short-wavelength opsins were repeatedly lost as various groups diverged (Fig. 1). SWS1 was lost in the monotremes, while marsupials and eutherians lost SWS2 instead. The Rh2 opsin is completely absent in all mammals, implying that it was lost sometime before the divergence of the mammalian ancestor (Jacobs 2013). Mammals have even lost the *opn4x* gene, which expresses photopigments in non-retinal tissues in other vertebrates, as well as several structures related

to melatonin production involved in the regulation of the circadian rhythm (Heesy and Hall 2010).

It has been suggested however that the long-wavelength cones may play some critical role, a nonvisual function, such as the circadian rhythm, considering its consistent retention in all mammals (Schwab 2012). The short-wavelength cones may therefore have few, if any, ancillary functions and would be far more sensitive to genetic drift in a changing sensory ecology. For example, despite their nocturnal niche, most bats have retained long-wavelength-sensitive opsins, but across species, short-wavelength opsins show considerable differential conservation (Simoes et al. 2019). Some species relying almost entirely on echolocation have lost the SWS1 genes completely, while others have retained some SWS1 function to augment their navigation with a small amount of short-wavelength vision (Zhao et al. 2009). Possibly lending credence to this argument is the apparent lack of abundance of short-wavelength-sensitive cones in most mammalian retinas. As many as 10% of all mammalian species have lost the SWS1-expressing cone subtype entirely, with the trend that these species have all currently inhabit, or have an ancestral history of inhabiting, nocturnal niches (Jacobs 2013).

Evolution of Mammalian Vision, The, Fig. 1 A simplified Cladogram showing the gradual loss of cone opsin classes across mammalian groups and the re-acquisition of trichromatism in new and old world monkeys. The

nocturnal bottleneck, represented by the grey box, marks a period of loss of cone opsin classes and subsequent increase in rod production

Seeing in Color

After the nocturnal bottleneck, following extinction of the dinosaurs, ancestral mammals were free to once again reclaim a diurnal lifestyle but were left with visual systems already adapted to their nocturnal niche. The loss of cone opsin genes had reduced the range of color discrimination from four color channels (tetrachromatic) down to only two (dichromatic). This loss was not immediate or entirely complete, as there is some evidence of progressive degeneration of opsin genes in more basal-branching mammals. For example, there is evidence of trichromacy in marsupials, though most are dichromats (Arrese et al. 2002). While extant species of monotremes are dichromats, a third nonfunctional opsin gene remains identifiable in their genome (Jacobs 2009). Such remnants of the ancestral state may reflect an intermediate stage of color vision loss. Among mammals, only the primates have acquired a true, consistent trichromatic vision. Some early-branching primates, like the lemurs of Madagascar and other “prosimians,” have maintained a nocturnal lifestyle and the dichromatism that came with it (Schwab 2012); however most extant primates have acquired a third cone opsin and regained trichromatic vision, though they’ve done so in markedly different manners.

In new-world monkeys, the callitrichids and the cebids, the X-linked LWS gene has developed several different alleles. This polymorphism allows for the production of an additional opsin with a slightly different spectral sensitivity in heterozygous females (Bowmaker 1998). Old-world monkeys, like the great apes and humans, derived trichromacy through a gene duplication event that resulted in two separate long-wavelength-sensitive opsins (in “red-sensitive cones”), one of which was free to mutate into a stable novel gene with a shifted spectral sensitivity (producing “green-sensitive cones”), allowing for trichromatism in both males and females (Bowmaker 1998).

The Value of Vision

The prevalence of dichromatism among mammals suggests that despite the restricted range of color

vision, it may not be entirely detrimental and could possibly even prove beneficial in certain circumstances. For example, it has been demonstrated that dichromatism is more likely to subvert color-based camouflage (Morgan et al. 1992), making it adaptive for finding well-camouflaged prey like insects among dense underbrush. However, to be considered adaptive, such advantages would need to outweigh those of trichromacy, such as locating brightly colored foods like fruits and leaves (Dominy and Lucas 2001), standing out to attract a suitable mate (Ryan and Keddy-Hector 1992), or detecting certain predators (Pessoa et al. 2014).

The organization of an organism’s visual systems may also be indicative of their lifestyles. Diurnal species tend to have cone-dominated retinas, though the distribution of these cones is far from uniform and is highly correlated to their ecological needs. Many species produce a circular area of the retina with an increased density of cones than the surrounding areas called an *area centralis* (Hauzman et al. 2018). This retinal configuration is often seen in species living in forests, where wide open lines of sight are less common and more focus is needed on the immediate surroundings. In the *area centralis* of birds, reptiles, and primates an area of even higher cone density sometimes forms a pit in the retina called a fovea. By displacing the surrounding supporting neural retinal cells, an increased surface area of the cone dense patch is more directly exposed to light (Bowmaker 2012). It is suggested that forming this pit magnifies the image-forming surface to improve visual acuity despite primates’ relatively low abundance of cones. This focused retinal surface, combined with large brains and complex neurological systems to integrate binocular signals, gives primates excellent depth perception (Barton 2004) – adaptations that could prove useful for climbing through the trees as well as for holding and manipulating nearby objects.

Many species do not possess an *area centralis*, but rather an elongated zone of increased ganglion cell and cone cell density that spans the horizontal or vertical axis of the retina (Bowmaker 2012). Rather than providing a single clear image, these “visual streaks” sample a panoramic view of the

surrounding environment without the need for much eye movement (Hauzman et al. 2018). The orientation of the visual field is strongly correlated with an organism's environmental niche. Vertical visual streaks are quite rare, found mostly in species with vertically oriented behaviors, such as certain fish migrating through the water column or sloths climbing along branches. Horizontal visual streaks are typically seen in species, e.g., rabbits, that inhabit open terrain such as fields. This arrangement allows consistent scanning of the horizon and responds strongly to fast-moving objects, rather than focus on any one location in particular (Levick 1967; Collin 2008), a critically important ability for detecting approaching predators.

Conclusion

The history of mammalian vision runs parallel with the history of mammals themselves. The vertebrate ancestor likely possessed four classes of cone opsin, spread between two single cone types and a double cone. However, shifting to a nocturnal lifestyle reduced the evolutionary pressure to maintain strong color vision, instead provoking a shift towards large eyes with rod-dominated retinas that resulted in a loss of several cone subtypes. Although they are now released from the nocturnal bottleneck, the evolution of mammalian visual systems has been shaped by the limitations imposed by an ancestral state that heavily favored visual sensitivity at the cost of acuity. Only the old-world primates, humans included, have managed to re-acquire stably heritable trichromatic vision, and all the benefits that come with it.

Evolution of Mating Systems

► Evolution of Long-Term Pair-Bonding in Humans

Evolution of Memory, The

Marios Constantinou

Department of Social Sciences, School of Humanities and Social Sciences, Nicosia, Cyprus

Synonyms

Adaptive memory; Evolution and memory; Memory and survival

Definition

The adaptive function of memory and its role in the survival and fitness of the humankind. Memory is the process of acquiring, storing,

and recalling/retrieving information either verbal, nonverbal, sensory, or emotional.

HM

HM at the age of 27 lost his ability to memorize new information. A neurosurgical operation succeeded to reduce his intractable epileptic seizures but left him with a dense memory loss, amnesia. In the 1950s we did not know the important functioning of the hippocampi, the structures removed in HM's surgery to reduce his epileptic activity. HM's global amnesia developed immediately, given that the bilateral surgical removal of his hippocampi caused him to lose the ability to form new memories. Later of course this finding about the functioning of the hippocampi was cross-validated with more case studies and animal studies. Of course, neurosurgeons from then on took extra care not to damage or remove hippocampi bilaterally as it was shown that this small structure, in the center of our brain, holds the secret of memory formation, in other words, the encoding of new information. What was even more remarkable in HM's case was that after the removal of the hippocampi, the newly learned explicit factual and verbal information, as well as memory about events, disappeared from his mind within minutes. However, he was still able to learn and remember newly learned motor movements and perceptual info, and he retained most information that he learned before his surgery (retrogradely; he lost memories made up to 11 years before his surgery, so he had memories up to the point he was 16 years old). HM's studies and all similar future research revealed to us areas of the brain related to memory and how learning, encoding of new information, and memory systems function.

What was evident from HM was that a person cannot survive all alone with bilateral damage in the hippocampi; in other words, a person without the ability to record new memories and learn new information is doomed not to survive, if not for the help of their family or community. If HM was born thousands or hundreds of years ago, his survival would have been really difficult, if not impossible.

Areas of the Brain Related to Memory

The amygdala is the center for memories involving emotions, while the hippocampus is the center of declarative (explicit), episodic, and semantic memories. Declarative memories refer to the store and recollection of factual conscious information, while episodic memories, a subdivision of declarative memories, refer to the store and recollection of our own personal factual information. Semantic memories, the second subdivision of explicit memories, refer to the store and recollection of general knowledge, which is not personal (autobiographical) in nature. Both the amygdala and hippocampus belong to a greater brain system called the limbic system.

Given the aforementioned information, extensive damage to the amygdala (bilaterally) generates lower levels or absence of emotions (such as fear), while memories related to emotions are impaired. Extensive damage to the hippocampus, bilaterally, leads to impaired encoding (registration of new information) and anterograde amnesia, the inability or impaired ability to store (and consequently recall) new information. Our amygdala and hippocampi are also responsible for consolidating our factual and emotional memories and moving them from short-term to long-term storage; therefore their damage impairs the consolidation of various memories and their conversion from short-term to long-term memories.

Another area of the brain, much larger than the ones already discussed, the cerebellum is the center for procedural and motor memories. For example, learning and remembering the procedure required to ride a bike would fall in this category or memories. Learning new motor and procedural skills, fine-tuning them over time via practice, and storing these procedures are functions related to the cerebellum.

The basal ganglia, a group of brain nuclei, are also involved in motor memories. Learning, storing, and recalling such information are functions relating to basal ganglia. The basal ganglia, however, are also involved in implicit memory, the creation and store of information that we might not be readily aware, and some scientists refer to these memories as subconscious memories.

Our frontal lobe, the largest lobe of the brain, is responsible for coordinating all of the aforementioned memory functions and is also responsible for our concentration (required to learn new information) and planning and organization, functions which are also important in learning and memorizing. Without our frontal lobes, it would not be easy to select the appropriate piece of information, at any given time, among all of our memories and stored information, in order to control our behavior in the best way possible and, therefore, search for memories and information crucial to our survival in some instances.

The frontal lobe is also responsible for controlling our working memory, our ability to retain some information for short periods of times and behave accordingly. For example, the short retainment of a math problem, which is read by a teacher, until it is solved and the answer is given, requires a good working memory. Finally, our frontal lobes, as they are the planning center of the brain, are responsible for our prospective memory, remembering what is needed to be done in the near or distant future, which is also crucial for our species success and survival.

The temporal lobe is the lobe that controls our ability to recognize pieces of information that we encountered in the past, a process plainly called “recognition,” which is not part of our aforementioned memory systems. For example, it is difficult to actively remember and recall the name of a historical person, who was mentioned 2 years ago in a documentary. However, it is much easier to recognize that name when somebody else mentions it or if you are asked to recognize it among multiple choices. This is what makes multiple choice questions generally easier, in school tests, than recalling information verbatim in written answers to essay test questions. The temporal lobe also mediates our memory and recognition of faces and mediates our learning, store, decay, and recall of verbal information. It is therefore obvious that recognition of information and recall of verbal of information could be also very important in our species sustainability. For example, when re-encountering a dangerous person or a dangerous animal that you could not recall their name or face/shape readily, you would quickly

recognize them, and you could quickly escape to save yourself.

The parietal lobe has a role, as well, in memory. It mediates our memories related to our sensations and perceptions. For example, memories related to physical pain and touch could be mediated by the parietal lobe.

Finally, the occipital lobe, the lobe that lies to the far posterior area of our brain, is the visual center; it mediates visual memories and is associated with learning visual symbols, such as letters and numbers.

Memory, Learning, and Evolution

Drosophila, a fruit fly, showed us that, through generations of the species, changes in the genotype are responsible for nervous system alterations, which could critically affect learning, retaining, and recall (Sherry and Schacter 1987). Evolutionary scientists are collecting evidence and hypothesize that similar changes, favoring our survival and reproductive success, developed our memory systems, related to specific brain loci, that will be discussed below.

The brains of reptiles and birds, and even mammals, are similar in that they are organized in some similar divisions and subdivisions (Kaas 2013). The two main divisions, namely, the cortex and subcortex (subcortical nuclear structures), have several subdivisions, as Kaas (2013) states, which are the lateral/side regions with olfactory control, dorsal areas with control of other sensations, and medial deeper areas that are in control of learning, memory, and recall. In primates, apes, and humans, the dorsal cortex evolved into a thicker structure, with humans having a very thick cortex (or neocortex) as compared to other mammals and primates. The neocortex, lobes of which we discussed above, take up the higher order processing of information, complex thoughts, sensations, and responses. Our medial structures continue, however, to be responsible for learning, memory, and recall of information; the aforementioned hippocampus is a very important memory medial structure. Through the years, our cortex became organized in layers and columns,

and our memory centers started communicating with these higher cortical areas that little by little gave rise to memory systems, which are the products of simultaneous synchronous functioning of cortical and subcortical areas.

“Human Memory is an evolved trait, fine-tuned over generations by the process of natural selection” (Nairne and Pandeirada 2016). All of our traits that are deemed favorable for our reproduction and survival are adopted; memory functioning and memory systems therefore have been evolving to suit our living, survival, and mating. Nairne and Pandeirada (2016) hypothesize that memory could have evolved from a simple perceptual processing into a complex function. They also conclude that recalling and memory decay creates an “adaptive behavior” selected to improve our fitness and chances of reproducing and surviving.

Recalling has apparent benefits for human beings, as learning and memorizing would not be useful without being able to recall information when needed. The decay of memories and learned information is also adaptive for human beings. This is evident in a rather cliché example, that of a woman, who gives birth might not attempt in the future to reproduce if the difficulties and pains of pregnancy remain vividly active in her mind long after giving birth. Similarly, a couple tends to remember mostly the happy times of raising a newborn, toddler, child, and teenager, otherwise vivid memories of the “bad times,” and often anguish related to raising difficult children or children with impairments, might be a deterrent for having more children.

All categories of information that we acquire, retain, and recall or forget are due to our memory, which allows us to learn and survive. Like history for humanity, memory is what allows us to remember past experiences, past hurtful situations, past positive livings, and adapt to our environments by taking advantage of what we already know. We solve the same, similar, or even brand-new problems based on our previous experiences and learned information, and we survive by remembering what is lethal, unwanted, or beneficial for ourselves.

It is not only our memory that is being perfected over generations but also all of our

cognitive systems such as sensations and cognitive perceptions (visual, auditory, tactual, etc.), our executive functions (such as planning, organizing, attending, and fluency), our language (comprehension and production), and every other aspect of our cognition that evolved in along and in an interplay with our memory. Of course, as we saw above, memory is often in a mutual exchange of information between other cognitive systems. For example, language comprehension and production depend on past learning but also the retrieval of words, idioms, and meanings in order to be effective.

Some of the first studies of learning were the biological research of Spalding on animal imprinting (Spalding 1873), which is a learning process through which animals during a critical age period (phase-sensitive period of learning) learn very fast a behavior, which is not contingent to consequences, as in operant conditioning. For example, in some birds it is the strong attachment association of a young chick with its caregiver or even the first moving object they see after their birth, most often their mother. Later Thorndike stipulated the relationship between a stimulus (S) and its response (R) and how this S-R learning is established by either the frequent or intense pairing of a stimulus and its response (Thorndike 1913, 1932). For example, the connections made by Thorndike’s cat between a lever (S) with escaping (R); a pairing which developed and strengthened the learning that the pressing of a lever leads to escaping from a confined space. Similarly, a child wanting a cookie throws tantrums and exhibits bad behavior having learned in the past (via S-R learning) that this behavior sooner or later will force the parents to give into her requests. Later, behaviorists recognized that the learning is not only based on S-R pairings but also on an organism’s individual internal processes which affect the learning process. This new behavioral notion became known as S-O-R (stimulus, organism, response). For example, an adult with better attention will learn faster or better a taught process at work than other colleagues with poorer attention or concentration difficulties. In Pavlovian classical conditioning (Moore 2004), the difference is that here learning involves not

only a stimulus (plus an organism) and response but also a pairing of an unrelated stimulus (conditioned stimulus) with the response. For example, the child in the previous experiment learns after several pairings of eating a cookie while watching cartoons, to associate a previously neutral stimulus (watching cartoons) with the need of having a cookie. Animals and humans also learn through operant conditioning where reinforcers and punishers increase or decrease the likelihood of a behavior occurring. For example, an animal that receives a treat every time it sits at command learns through operant conditioning. Finally, animals and humans alike learn via observation (modeling or social learning), and a cat that sees another cat hunting to eat could learn better hunting techniques itself or how to hunt altogether. All in all, the type of learning is imperative in our encoding (learning), memorizing, and remembering/recalling how to behave in certain environments, instances, and ultimately to our survival.

A very recent approach to understanding mental health in humans studied language and its evolution in humans. The most distinctive characteristic that we developed as humans is exactly that, language (Sherwood et al. 2008). Arguably, and according to acceptance and commitment therapy (ACT), humans make verbal associations continuously, and these verbal associations may lead to connections of words, circumstances, and places with happiness (e.g., a friend's name that could instigate happy feelings), sadness (e.g., passing by a road that brings about terror and thoughts of doom because it was associated with an accident), or any other feeling. These verbal associations of course happen always in a context. Relational frame theorists (RFT), who stipulate this theory, said that "...the core of human language and cognition is learning to relate events mutually and in combination not simply on the basis of their formal properties (e.g., size, shape) but also on the basis of arbitrary cues" (Hays et al. 2013). Therefore, the development of language in humans not only helped us in communication but also in recalling (consciously or subconsciously) associated feelings with objects, people, animals, circumstances,

etc. that could be vital to our survival. For example, verbally associating a viper snake and its habitat with feelings of doom and danger after watching another person being bitten and later dying will most definitely help us actively avoid such encounters. Often we overgeneralize through mental verbal associations that lead to non-adaptive learning. Following the previous example with the snake, such associations/learning may not be ultimately adaptive as our newly learned associations may lead us to avoid all snakes (beneficial or not) and entire fertile areas (which could lead to better crops) that we verbally associated in our mind with danger (the viper). This association and learning could have happened because of one and only specific experience, meeting a dangerous viper.

The understanding of memory systems and memorization, learning, and recalling became even more robust in the past few decades as neuropsychology started adopting memory tests from primate experiments for humans and also developed new memory tests (Murray et al. 2017). Neuropsychology developed rapidly following the two world wars when wounded soldiers with traumatic brain injuries were returning home in the thousands with cognitive impairments, which were not fully studied up to that point. Neuropsychology, the study of brain behavior associations, evolved itself into clinical neuropsychology (American Psychological Association 2010) that determines, through thorough cognitive assessment, the cognitive impairments caused by transient (e.g., medication or a mental disorder) or permanent (e.g., chronic adrenal disorder or diabetes) environmental and organic reasons or by direct brain lesions and damage following a traumatic brain injury or surgery. What is evident in clinical neuropsychology is that brain lesions, brain damage, and transient or permanent environmental factors affect most often memorization, recalling, attention, and concentration and less often other faculties and brain functions. The hippocampus, in particular, is a very sensitive structure in the brain that is among the first to be negatively affected by environmental or organic causes of brain abnormalities (Anand and Dhikav 2012).

Memory Systems

Memory is not just one unified system or faculty, as previously discussed, but multiple systems, and each one of them controls or mediates a memory function (Poldrack and Packard 2003). However, these systems do not exist in isolation, even though they can work independently (Sherry and Schacter 1987). They also interact with each other in order for us to encode, learn, move information to short- and long-term memory, and recall that information. At the same time, there are times when memory systems compete with each other; in a simplistic example, trying to memorize a particular location while driving could be negatively impacted by the encoding of emotional stimuli (e.g., fear, panic, etc.) which could lead to the encoding of other types of information that suddenly appeared during the process of memorization of a location. Memory in human beings has been evolving into different memory systems and different structures in the brain (as mentioned above) assumed, through evolution, the control or organization of these different memory systems. Memory systems are defined as “. . .an interaction among acquisition, retention, and retrieval mechanisms that is characterized by certain rules of operation. . .” (Sherry and Schacter 1987).

According to Murray et al. (2017), the development of neuroscience and neuroimaging (e.g., fMRI, MRI, CT scans, spectroscopy, etc.) allowed neuropsychologists and neuroscientists to make clinical correlations between damaged brain areas and their neighboring surviving brain areas with memory systems. In addition, Murray et al. (2017) present in a table the neuroscientifically accepted memory systems along with the brain areas associated with them. Specifically, the memory system that involves our personally learned habits' system is associated with the basal ganglia, whereas our explicit memory system is associated with the temporal lobe (medial structures). In addition, according to Murray et al. (2017) our emotional memory system is associated with the amygdala and our motor memory system is associated with the cerebellum. Finally, our priming of behavior's system is associated with the sensory cortex.

Apart from the memory systems, and the brain loci associated with each one of them, which were described by neuroscientists, evolutionary cognitive scientists recognize seven memory systems, according to Murray et al. (2017). These systems developed through evolution to aid our survival. These are:

1. Reinforcement memory system, which describes memories made via contingencies (stimuli, responses, and outcomes) and solidified with reinforcers
2. Navigation memory, which refers to our memories that help us find our way through our environment
3. Biased-competition memory, which is formed via competitive stimuli and representations and allows us to differentiate among already existing representations engraved in our memory and new ones
4. Manual-foraging memory, which developed following the locomotion in two legs that freed the arms and hands for feeding and action, while vision helps find and select what the individuals deems as valuable
5. Feature memory, which categorizes stimuli and information into their individual characteristics of color, shape, weight, surface, etc.
6. Goal memory, which helps us remember objects, places, etc. and associate them with actions, targets, and behaviors for achieving goals and plans
7. Social subjective memory, which are stores of representations of ourselves and representations of other individuals that help us in our socialization and self-awareness

In a more classical cognitive psychology view of memory and learning, different types of memory, as assessed in cognitive and neuropsychological assessments, are also viewed as different memory systems, as well (Squire 2004). In this article, declarative memory, defined at the beginning, is one memory system divided into semantic and episodic memories. A second memory system named nondeclarative memory involves our procedural memories (skills and habits), classical conditioning, nonassociative learning (reflexes),

and priming and perceptual learning (Levy et al. 2004). Priming and perceptual reasoning were not previously defined and refer to learning that is aided by previous experiences associated with new learning material. For example, a student memorizes and remembers better the word “needle” if it follows the word “vaccination” in a word list that needs to be memorized through rote memorization (memorization through repetitive exposure to stimulus).

Conclusion

The evolution of our memory (visual, auditory, olfactory, and tactile memories) and memory systems are definitively crucial to our survival as species. Our memory and memory systems will keep evolving and most probably, at some point, they will include more memory systems and functions that adapt to the great technological advances that humanity has been experiencing, since the industrial revolution, along with the vast digital advancements that we are experiencing nowadays.

[Ethics](#); [Morals](#); [Right and wrongs](#); [Righteousness](#); [Virtue](#)

Definition

The Evolution of Morality is the development and transformation of moral behavior or thoughts across the course of human evolution.

Introduction

Morality is a crucial component to humanity and society (Haidt 2012). In particular, morality provides individuals with a set of rules that allow them to live together in relative harmony. Despite the awareness of morality's significance, one of the most frequent questions in moral psychology is where does morality come from? Consequently, the purpose of this entry is to provide a brief overview regarding the origin and various foundations of morality. Lastly, this entry will conclude with recent advances in moral psychology by focusing on Moral Foundations Theory as well as suggestions for future research.

Morality

Morality can be defined as a system of “interlocking sets of values, virtues, norms, practices, identities, institutions, technologies, and evolved psychological mechanisms that work together to suppress or regulate selfishness and make social life possible” (Haidt and Kesebir 2010, p. 800). Morality is also an evolutionary adaptation that can be thought of as a form of social behavior (Allchin 2009; Haidt 2012). For example, the most intricate animal societies develop morality in order to promote and maintain group cohesion, decrease the likelihood of harm, and increase the likelihood of group success. Taken together, morality is a highly social process because many of the motives, behaviors, and values that are associated with morality concern social benefits (e.g., mating, nesting, protecting one's territory; Allchin 2009).

The Sources of Morality

Individuals often argue that morality has its origins in either nature or nurture (Haidt 2012). A *nativist* is an individual who believes that morality is innate and comes from nature. For example, nativists may argue that morality was implemented by a higher power (e.g., God) or perhaps evolved intuitively or emotionally. In contrast, an *empiricist* believes that the mind is a

blank slate at birth and that morality emerges during the socialization process. An empiricist may argue, for example, that morality develops as children learn the differences between right and wrong from adults in their social environment.

There is also a third possibility regarding how morality develops which is often referred to as *rationalism*. Rationalism refers to the belief that morality is neither innate nor learned from adults but is self-constructed from experiences (Haidt 2012). More specifically, a child learns to be moral through experiences of harm and fairness, which allow the child to solve complex moral problems as he or she develops (Piaget 1932). In sum, rationalists believe that the final stage of moral development is when an individual is able to engage in socially acceptable moral reasoning (Haidt 2012).

However, many of these answers have been rejected due to recent research. In particular, morality cannot be entirely innate because it has been found to vary by culture (Haidt 2012). For example, in some cultures the aspect of purity has been found to be a significant part of the moral compass used in some cultures but a relatively weak aspect of morality in other cultures (Haidt 2012). Furthermore, individuals have been found to experience gut feelings (i.e., intuitions) when faced with moral dilemmas which suggest that morality may not be based entirely on socialization (Haidt 2001).

Dual Process Model of Morality

Recent advancements in morality research suggest that morality develops from a set of evolved intuitions that are innate, but there is a strong socialization component because children learn how to apply these intuitions within their particular culture (Haidt 2012). More specifically, nature provides the first draft of morality, but this initial version of morality is malleable which allows it to be shaped by the socialization process (Marcus 2004). Haidt (2001) proposed the *social intuitionist model of morality*, which is an approach that rejects one of the former views regarding the development of morality (i.e., the rationalist view) – the model combines the importance of

evolved intuitions as well as the significance of social and cultural forces. For example, when an individual is presented with a moral dilemma, he or she will first experience an immediate gut feeling (i.e., a moral intuition) which may then elicit a moral judgment (i.e., good or bad evaluations; Haidt 2001). However, when an individual's moral judgment has been challenged he or she may engage in moral reasoning (Haidt 2001). For instance, if an individual is asked to explain his or her moral decision, then he or she will often develop something akin to an "inner lawyer" that will attempt to provide an explanation for the relatively intuitive moral judgment (Haidt 2001). Lastly, this moral decision-making process can be modified depending on one's social environment (e.g., peer influence) and culture (i.e., some cultures emphasize different moral intuitions; Haidt 2001).

This model of morality can also be thought of as a dual process model (Haidt 2012). More specifically, moral intuition – which reflects an automatic process – comes first and may be followed by moral reasoning – which is a controlled process – if this sort of cognitive action is required (Haidt 2012). Moral intuitions are fast, effortless, and linked to motivation, which can strongly influence one's behavior (Haidt 2012). In contrast, moral reasoning is a more recently evolved ability that relies on cognition and language-based reasoning (Haidt 2012). Many theorists have argued that one of the main reasons for the evolution of language was to keep track of the behavior of other individuals (Dunbar 1998) and to improve reasoning (Haidt 2012). However, the controlled process is slow and effortful which may contribute to the automatic process serving as the default process (e.g., Haidt 2001, 2012). Consequently, in order for an individual to change his or her moral judgments, he or she must develop new moral intuitions (e.g., Haidt 2001, 2012).

The Five Moral Intuitions

The Moral Foundations Theory specifies that humans have been equipped by the evolutionary process with a set of automatic moral intuitions, but these moral intuitions are malleable and can be altered by social and cultural influences (Haidt

2012). Haidt and Graham (2007) argued that there are five basic moral foundations: Harm/Care, Fairness/Reciprocity, Ingroup/Loyalty, Authority/Respect, and Purity/Sanctity. The Harm/Care foundation concerns the suffering of others and evolved in order to elicit a caring and sensitive response to help those in need (Haidt 2012). The Fairness/Reciprocity foundation evolved in response to the adaptive threat of being exploited by cheaters and increasing one's chances of receiving benefits of cooperation (Haidt 2012). The Ingroup/Loyalty foundation evolved in order to maintain group cohesion by making an individual aware of others that want to hurt or ostracize members of the group (Haidt 2012). The Authority/Respect foundation evolved in response to maintaining and respecting social hierarchies – this foundation makes us aware of any potential threats to one's status or rank (Haidt 2012). Lastly, the Purity/Sanctity foundation evolved in response to the danger of pathogens and parasites – this foundation includes the behavioral immune system, which makes individuals aware of any potential threats to symbolic objects or values (Haidt 2012).

These five moral foundations can be separated into two higher-order factors that are referred to as *individualizing* (i.e., Harm/Care and Fairness/Reciprocity foundations) and *binding* values (i.e., Ingroup/Loyalty, Authority/Respect, and Purity/Sanctity foundations). Past research has shown that political ideology is associated with certain moral values that people adopt (Haidt and Graham 2007). For example, liberals have been found to be more concerned with individualizing foundations, whereas conservatives are more likely to adopt binding foundations. In addition, pathological personality features (e.g., antagonism) have been found to be negatively associated with specific moral values (e.g., individualizing values; Noser et al. 2015). Taken together, there are important individual differences that may further explain moral intuition and reasoning.

Conclusion

Morality plays a vital role in the social lives of individuals and is crucial for the functioning of

society. Morality has its origins in innate beliefs but the moral system is complex and it can be cultivated depending on social and cultural contexts. Moral Foundations Theory provides a framework for considering evolved moral intuitions, but future research may benefit from considering the possibility that other moral foundations exist. In addition, more research is needed that goes beyond self-report to capture actual behaviors in situations that involve moral judgments.

Synonyms

[Adaptive play behavior](#); [Phylogeny of play behavior](#); [Play as adaptation](#)

Definition

Play behavior can be studied as an adaptation evolved to develop motor and problem-solving skills, assess one's own capabilities in relation to one's environment, and learn how to interact and perhaps cooperate with social partners; play can also be considered phylogenetically as a trait that has evolved divergently, convergently, and in parallel.

Introduction

Play behavior can be observed across much of the animal kingdom, especially in the mammalian lineages. The prevalence of play suggests that play behavior could be a behavior that has evolved to be adaptive, but developing and testing hypotheses to explain its origins has proved challenging. Understanding play behavior from an evolutionary perspective requires that play be clearly defined, that we have clear hypotheses explaining the relative costs and benefits of play, and that these adaptive hypotheses can be tested through direct or indirect observation. This entry explores how ethologists have observed and defined play in a variety of animal species (including humans) and how play has been explained from an evolutionary perspective. The evolution of play has been investigated through the methods of ethology and phylogenetics, both of which will be reviewed here. As the most playful species on the planet, humans have much to learn from studying both human and nonhuman play from an evolutionary perspective.

Why Play?

Why did play behavior evolve? It is tempting to assume that play emerged because it immediately provided benefits. But play is most likely to have emerged as a by-product of other adaptive behavioral processes, a by-product that would eventually be co-opted to serve new functions (Pellis et al. 2015). That play probably evolved via circuitous evolutionary routes makes it all the more difficult to ascertain whether our questions should be about how play emerged (What were the original processes that led to the appearance of play behavior?) or why play persisted (What functional value might allow a by-product to evolve into a benefit?).

Although it is possible that some of the play behaviors we observe today are still a by-product of other adaptive behaviors, many forms of play may persist because they are adaptive. By definition, a behavior is an adaptation if it increases an individual's chances of surviving and reproducing

relative to alternative behavioral options. Playing sometimes seems like a waste of time, or inordinately risky, because play behaviors don't always provide immediate benefits: play is frivolous, a luxury. How might play increase the overall prospects for survival and reproduction? What benefits offset the costs of play, and when/how do these benefits appear? How have organisms evolved to respond to particular environmental conditions by playing? How is play related to development and the attainment of reproductive maturity? Why are some species prolific players, while others do not play at all? Understanding play from a Darwinian perspective requires that we address these questions.

Costs of play: Play is a behavior with clear potential costs. There could be an opportunity cost associated with play behavior, as it sometimes produces no immediate benefits: time spent playing could be spent resting, searching for a mate, or finding resources. Many forms of play are physically demanding and therefore come with an energetic cost. Because play is immersive and often occurs in open spaces, it can leave individuals more exposed to predators. Many forms of play involve risk-taking, making injury a potential cost as well. The fact that there are so many measurable risks of play behavior makes it all the more important to establish what benefits might have driven the evolution of play.

Play as an evolutionary paradox: Play is an apparent paradox because sometimes it appears, on first assessment, to be a wasteful behavior. Why would an animal expend energy, exclude itself from more immediately productive activities, and expose itself to increased risk if playing provides no direct or immediate benefits? So long as the benefits of play remain unquantified, play appears to be an evolutionary paradox. This paradox can be resolved if play behaviors lead to indirect or delayed benefits that are large enough to offset the immediate costs of playing. Since many forms of play have little immediate function, it is important that potential benefits be measured after play has occurred; how long it takes for these benefits to be manifested depends on the life history of the animal as well as the kind of play that that animal engages in.

Benefits of play: Numerous benefits of play have been suggested, but most fit into one of seven broad categories. Play can be used to:

1. Contend with negative cognitive processes
2. Develop motor skills
3. Train for the unexpected
4. Assess one's own physical and cognitive capabilities
5. Assess the reliability and capabilities of potential social partners
6. Learn social norms
7. Foster social cohesion

Play may simply be a way for animals to reduce anxiety or to escape boredom, suggesting that during lower-stress intervals play may help animals contend with evolved cognitive processes that are more geared to the most rigorous elements of their environment. Some animal species maintain plastic neurological systems that allow for the development of motor skills through the practice that play can provide; such developmental employment of play is particularly common in juveniles. Whereas developing motor skills involves training for normal or expected behavioral responses; it is also possible that the spontaneous and uncontrolled nature of play may train animals to respond to unexpected environmental conditions. Play may be a means by which animals can assess their own capabilities in relation to prey, competitors, or predators; such assessment may enable animals to manage the behavioral balance between risk and reward in varying environments. Play may also be a means of assessing the capabilities of potential social partners; such assessment is crucial for animals which choose to work cooperatively with particular members of their social group. For species whose survival depends on social interactions, play can be a means by which young animals learn the norms that govern those interactions. And in species where social cooperation is important, play can be a means by which individuals form the bonds that create a cohesive social group.

While each of these potential benefits is distinct from the others, particular forms of play can provide more than just one of these benefits. An

animal batting around an inanimate object may be both developing better predatory motor skills and gaining an understanding of what sorts of prey it is capable of actually catching. Play-fighting may develop motor skills (for example, to escape predators) but in addition may allow individuals to assess the capabilities of their social partners and create the social cohesion necessary to foster social cooperation.

It is relatively easy to observe play behavior and hypothesize various benefits it might provide, but testing these hypotheses by observing the increases in fitness they predict is more challenging (Burghardt 2005). Studies of horses (Cameron et al. 2008) and bears (Fagen and Fagen 2004) have demonstrated that the degree to which animals play as juveniles positively correlates with their prospects for survival to adulthood. Juvenile Belding's ground squirrels that played more often scored higher on tests of motor skills (Nunes et al. 2004). Playing as juveniles increased the resiliency of elephant calves and increased their probability of surviving as adults (Lee and Moss 2014). A study of captive mink showed that increased rough-and-tumble play correlated with optimal adult sexual behaviors in both males and females (Dallaire and Mason 2017). Perhaps the most extensive studies of the benefits of play behavior have been carried out in rats, where play deprivation has been shown to be associated with social impairments, cognitive deficits, and increased anxiety-like behaviors (Vanderschuren and Trezza 2014). Further study is required to causally link play behavior to one or more of the benefits outlined above and ultimately to increased probabilities of survival and reproduction. When they are rigorously assessed, play benefits are often found to be lacking where they were hypothetically imagined, further reinforcing the need to empirically test adaptive hypotheses.

When play should evolve: Evolutionary theory suggests that play behavior should persist when the benefits of that behavior exceed its costs, with both costs and benefits measured as changes in the probability of surviving and reproducing. The benefits and costs of play may vary in different environments. In particular, resources may play a role in modulating costs

and/or benefits: in a resource-rich environment, the opportunity costs of playing may be reduced, while the potential benefits of playing may increase. For this reason, animal parents may invest in their offspring in ways that optimize the cost-benefit ratio of play (Cameron et al. 2008), allowing play to evolve as a critical component of normal physical and social development.

Hypotheses explaining why play evolves: The potential functional benefits of play imply hypotheses about why play has evolved in various species; nonfunctional hypotheses are also potentially important, especially if play behaviors represent a by-product of other adaptive traits. Spinka et al. (2001) considered their own hypothesis (*training for the unexpected*) alongside three other functional explanations (*motor training*, *self-assessment*, and *surplus energy*) and one by-product explanation (*surplus resources*). They then created a framework for comparing the relative support for each hypothesis by delineating 24 predictions that created strong contrasts between each hypothesis. Interestingly, their framework of comparison did not explicitly address some of the hypothesized social benefits of play (although if conceived broadly, “training for the unexpected” can produce benefits that relate to social norms and cohesion).

Testing the predictions made by different hypotheses: Understanding how play evolved requires that alternative hypotheses make clear predictions and that these predictions be testable. Hypotheses explaining the evolution of play can be applied to specific play behaviors in particular species or to play behavior across the animal kingdom (e.g., Spinka et al. 2001), although the diverse nature of play makes it unlikely that a single hypothesis will explain all instances of play behavior (Burghardt 2014). Even within a particular species, more than one hypothesis may be required to explain the full breadth of play behavior; for example, Sommerville et al. (2017) reviewed the literature on play behavior in domesticated dogs and discovered strong support for the predictions of both the *motor skills development* and *social cohesion* hypotheses. In considering why adult dogs play, Bradshaw et al. (2015) reached a similar conclusion and suggested that

different forms of dog play behavior may actually have independent evolutionary origins.

The prospect of studying play from an adaptive perspective is exciting, as doing so could resolve the apparently paradoxical nature of play. Play can have an ultimate function, even if it seems frivolous at the time. But in order to study play behavior scientifically, we need a clear definition of what kinds of behaviors constitute play. We can roughly identify play by its characteristics: it is fun, it is done for its own sake, and it is done in times and places that feel safe. But actually distinguishing play from non-play behaviors is not so simple and has presented a challenge to scientists who study play.

Defining Play (Is Not So Easy)

What is play? As an extremely playful species, humans ought to be able to identify play when we see it. But play turns out to be very difficult to precisely define. One reason that play can be difficult to identify is that it takes many forms and can serve many functions, making it a “heterogeneous” behavior requiring a fairly broad definition. Play behavior itself is often separated temporally and spatially from the benefits it can provide, making it more difficult to determine whether an observed behavior should be called “play.” Play behaviors are often defined by an affective state (“having fun”) which itself is difficult to define (or directly observe). That humans are as a species so playful also complicates our ability to determine what defines play; our tendency to anthropomorphize the behavior of other animals may produce definitions of play that are too inclusive, whereas our tendency to take a very anthropocentric view of our own behaviors can produce definitions of play that are too exclusive. For play to be studied scientifically, a clear definition is required.

Many (conflicting) definitions: Play has been a subject of serious study for well over a century, but researchers examining play have failed to come to consensus on a definition of what constitutes play (Burghardt 2005). There is disagreement over whether play is productive or a waste

of time, whether it is pro-social or antisocial, and whether it is safe or dangerous. Some researchers argue that play is not definable and therefore beyond scientific study, whereas others seek to define play as a behavior that can be studied from a Darwinian perspective.

Some of the conflict over how (and whether) to define play emerges from the different approaches of the ethological and psychological sciences. Whereas ethologists rely on clear behavioral distinctions that do not require knowledge of the internal state of the animal performing that behavior, psychological definitions may emphasize the private experience that underlies behavior (Brown 2009).

Burghardt's five criteria: To mitigate some of the confusion over what constitutes play and to advance the study of play from an evolutionary perspective, Burghardt (2005) advanced five criteria to define play behavior. These criteria are briefly summarized as:

1. Limited immediate function
2. Endogenous component
3. Structural or temporal difference
4. Repeated performance
5. Relaxed field

That play behaviors have *limited immediate function* hinges on the idea that the evolved benefits of play are indirect or delayed; although not all behaviors that fail to produce immediate benefits should be considered play, the absence of clear immediate benefits sets up the possibility that a behavior could produce delayed benefits. Behaviors with an *endogenous component* are performed in a manner that is not simply a response to external stimuli; Burghardt defines these behaviors as "spontaneous, voluntary, intentional, pleasurable, rewarding, reinforcing, or autotelic." To display *structural or temporal difference*, a play behavior must differ in some manner from other behaviors that serve a more direct functional purpose; many play behaviors are performed partially, in an exaggerated form, or in different times and places than analogous non-play behaviors. *Repeated performance* implies that during some point in the development of an animal, a particular behavior is practiced, often in

a progressively varying manner. Finally, play behaviors are performed in a *relaxed field*, which is to say that animals only play when they are healthy, their basic needs are met, and they are free from intense stress or competing motivational processes. A key aspect of Burghardt's five criteria is that they are interactive: while no single criterion sufficiently filters play from non-play behaviors, applying all five criteria can produce a relatively clear distinction.

Categories of play: Ethologists who study play have conceptualized three main categories of play behavior. *Locomotor-rotational play* includes various forms of body movements performed independently by individual animals. *Object play* involves the manipulation of objects found in the environment. *Social play* occurs when two or more animals interact as part of the play behavior.

These categories of play are not mutually exclusive: in fact, it is possible to imagine all three co-occurring in particular contexts. For example, wild bottlenose dolphins have been observed numerous times surfing waves into the shore, usually independent of feeding or any other behavior with direct function (Paulos et al. 2010). Surfing by dolphins is definitely a form of locomotor-rotational play because it requires that dolphins practice body movements that produce the ability to ride the wave. It could also be a form of object play where the wave itself is the object that is played with. And if dolphins surf together, having to maintain safe distance to avoid collisions with groupmates, then surfing could also be a form of social play.

Many forms of human play also simultaneously encompass all three forms of play. Consider a group of people at the park throwing around a flying plastic disc. This play is most obviously object play, as the players must learn how to throw and catch the disc. But learning how to play with the flying disc also involves locomotor-rotational play, especially in catching errant throws from less experienced players. And as with any game of "catch," playing with a flying disc is an inherently social activity that requires players to empathize with and anticipate the needs of their playmates.

Levels of play: A number of play researchers have suggested that play should be considered along a continuum of hierarchical levels. These include Robert Fagen's five levels of play, which emphasize the complexity of social interaction involved in play, and Robert Mitchell's four levels, which emphasize the degree of simulation and intent involved in a particular form of play (Burghardt 2005). Both of these classification schemes recognize that solitary play differs from play that is done in parallel or direct interaction with other individuals and consider social play to be more sophisticated than solitary play.

Particularly human extensions of animal play: The diversity of human play presents particular challenges to any categorization scheme. In addition to engaging in play behaviors that can be classified as locomotor-rotational, object, or social, humans also engage in forms of play that involve creative exploration, mental simulation, and complex roles. Some of these behaviors differ from other animals in extent, but others appear to differ in kind. It has been argued that many animals maintain rules of play (Bekoff and Pierce 2009), but no other animals play employing the complex rule sets of organized sports or strategy games. While it may be impossible to fully ascertain the degree to which other animals perform mental simulations and pretend, the unique complexity human language and – more recently – audio and visual technologies creates the potential for unrivaled levels of play that emerges predominantly within our brains. Play is a major source of innovation (Bateson 2014), and it is innovation that drives the human species' unique form of cumulative culture. To more fully encompass the diversity of human play forms, many researchers employ additional categories such as “free,” “creative,” “narrative,” and “reenactment” (Dallaire et al. 2017).

Differentiating play from other functional and dysfunctional behaviors: A number of common animal behaviors should not be considered play despite sharing some of the characteristics that typify play. Humans often associate being playful with exploration and pursuits that satisfy our curiosity. While exploratory behaviors motivated by curiosity can be forms of play, it is

important to recognize that many forms of exploration more closely resemble stalking or vigilance behaviors (Burghardt 2005). An animal may intensely examine a new enclosure or novel environment, but such an examination could simply provide valuable information about where to find resources or where to avoid exposure to aggression or predation. For exploration to constitute play, it must be repeated in some manner and occur in a low-stress environment.

Animals sometimes display behaviors that are maladaptive rather than adaptive and therefore do not constitute play. For this reason, stereotypies such as continual pacing and excessive grooming should not be considered a form of play. That such dysfunctional behaviors have almost exclusively been observed in the radically different environments created by captivity suggests that perhaps stereotypies could result from a mismatch between evolved play responses and the unnatural environments created for other animals by humans.

Four perspectives on play behavior: As with all forms of animal behavior, it can be useful to consider play behavior from Tinbergen's four perspectives. The first perspective considers the *proximal cause of the behavior* and requires that we examine both the role of external stimuli and internal neural states in prompting play behavior. Internal proximal causes of play such as “having fun” are assumed to be the product of evolution and imply that play is an adaptive behavior, but simply looking at the proximal cause of a behavior cannot illuminate how or why it may have evolved. The second perspective considers the life history of play (development of behavior throughout an individual's lifespan) and can be highly relevant to considerations of how juvenile play can produce adult benefits. The third perspective is perhaps the most crucial to adaptive studies of play, as it seeks to understand the function of behavior. That play behaviors produce benefits that are indirect or delayed makes accurately assessing their function more difficult but also crucial to differentiating play from non-functional or dysfunctional behaviors. The fourth and final perspective addresses how a particular form of play evolved and can range from

considering play as an exaptation of ancestral behaviors to putting particular forms of play in a phylogenetic context.

Evolution of Play in Nonhuman Animals

Although animals that play are relatively rare in all but a few taxonomic groups (such as primates, canids, cetaceans, parrots, and corvids), a diversity of play behavior has been observed across an intriguingly broad spectrum of animals. All three of the major forms of play (locomotor-rotational, object, and social) are prevalent among those species that display play behavior; what is less clear is the degree to which nonhuman animals engage in various forms of play that require mental simulation (e.g., pretending, imagining, creative planning). Considering the diversity of play in animals can shed light on both the functional origins of play and the evolutionary processes that yielded species that play.

Examples of animal play: The sheer number of different kinds of play behavior that have been observed in animals highlights both the importance and heterogeneous nature of play. Although relatively few invertebrates play, a few notable exceptions are worth mentioning. Spiders of the species *Anelosimus studiosus* engage in non-conceptive “sexual play” that enhances the fitness of both male and female players (Pruitt et al. 2012). Among invertebrates, octopuses are the champion players, the subject of many anecdotal accounts of playful behavior in the wild. Captive studies have shown that when provided with objects constructed from Lego toys, most octopuses of the species *Octopus vulgaris* will play with the objects (Kuba et al. 2006). Many ethologists have been skeptical that invertebrates can display play behavior, but in both of these cases, the observed behavior met all five of Burghardt’s play criteria, showing the value of employing objective play criteria to separate our anthropomorphic biases from our interpretation of behavioral observations.

Although birds and mammals are the most prolific animal players, other vertebrate lineages also display play behaviors. Cichlid fish have been observed to push around weighted

thermometers in aquarium environments (Burghardt 2014). Many species of fish repeatedly leap over each other and also will bat around floating balls left in their enclosures (Burghardt 2005). Fagen (2017) has suggested that particular forms of salmon jumping should be considered play. Poison dart frogs engage in rough-and-tumble play, and tadpoles have been observed to ride the bubbles produced by aquarium aerators.

Play has also been observed in reptiles. Dinets (2015) reports that crocodilian species engage in locomotor play (mostly associated with riding currents or waves), object play (involving streams of water or floating objects), and even social play (giving each other rides, rough-and-tumble play with other species). Komodo dragons engage in object play that is reminiscent of domesticated dogs (Burghardt 2005). Some species of aquatic turtles will play in captivity with floating objects and engage in tug-of-war bouts with their keepers (Burghardt 2005).

Many bird species engage in either locomotor, object, or social play with some orders (woodpeckers, parrots, songbirds, and raptors/pelicans) displaying all three kinds of play (Burghardt 2005). Many predatory birds engage in the playful dropping and recatching of objects in midair. Aerial play is also common in birds, which will ride currents of air and perform acrobatics independent of any attempt to catch prey, avoid predators, or defend territory. Many birds play with various useless objects, which may aid in the development of later functional tool use and/or caching behavior. Social play is less common among birds, but two taxa – the parrots and the corvids – play together. Parrot species, which live in groups, initiate play-chases and play-fights (Diamond and Bond 2003). Ravens engage in social object play in which two individuals will play tug-of-war over a stick (Heinrich and Smolker in Bekoff and Byers 1998). Corvids and parrots possess a highly encephalized brain in comparison to other bird orders, suggesting a parallel with the most playful mammal species (Osvath et al. 2014). The playful nature of these species may also explain their exceptional ability to solve problems in both natural and laboratory settings (Bateson 2014).

Mammalian play is diverse, commonplace, and relatively well-studied. Marsupials play with locomotor and social play being more common than object play. Kangaroos and wallabies engage in all three forms of play, including play-fighting, manipulation of found objects, and rapid-motion locomotor play (Watson in Bekoff and Byers 1998).

Play is even more common among the placental mammals. Pronghorn males join sparring matches that simulate actual fighting but mitigate the risks of real aggression (Miller and Byers in Bekoff and Byers 1998). Both wild and domesticated horses play as juveniles, running alone or in groups and sparring with others in their band (Cameron et al. 2008). Elephants play as juveniles and adults, both alone (manipulating objects, mud, dust, or water with tusks, trunk, mouth, or feet or running/spinning/rocking/kicking) and socially (wrestling, sparring) (Lee and Moss 2014). Bears will wrestle and chase each other, manipulate objects, and play through locomotion and body rotation (Fagen and Fagen 2004). Mustelids are highly playful, primarily engaging in juvenile rough-and-tumble play that is crucial to the development of normal social behavior (Dallaire and Mason 2017).

As a marine mammal taxon, cetaceans demonstrate the great potential for play in aquatic environments (Paulos et al. 2010). Whale and dolphin locomotor-rotational play includes erratic swimming, aerial leaps/breaches/flips, intentional self-stranding, and surfing on waves. Object play is also common in both the wild and in captivity: bowhead whales play with floating logs, various dolphins play with bubbles they create a variety of cetaceans play with both natural and human-made found objects, and orcas and a few other dolphin species have been observed playing with prey items. Cetacean social play in the water resembles social play in terrestrial mammals: young whales and dolphins are especially fond of chasing and bumping each other and performing aerial behaviors in synchrony. Another fascinating aspect of dolphin play is how often it includes other species, including birds, sea turtles, other cetaceans, and sea lions (Kuczaj and Eskelinen 2014).

The prominent role of play behavior in the development of primates has been appreciated

for longer than in any other taxonomic group. This appreciation likely emerges from both how playful primates are and a certain degree of anthropomorphic interpretation of play behavior in other species. Every species of primate whose behavior has been marginally observed displays at least one type of play behavior (Burghardt 2005). The play of chimps and bonobos – our closest primate relatives – is of particular interest. Both chimps and bonobos engage in locomotor-rotational and object play, but social play is the most commonly observed form of play. Juvenile social play is similar in both species, but there is a marked difference in frequency and type of adult play: bonobo adults play more, perhaps because their social structures require more of the kind of social grooming and bonding that regular play can provide (Palagi 2006). Some forms of bonobo play involve remarkable forms of risk and trust. Bonobos play the “ball game,” a form of chase in which a male “leader” trusts his play partner to gently grasp his testicles while both circle around a tree or bush. Bonobos also play trust games such as the “hang game,” in which one individual swings another by the arm from an elevated tree branch.

Rodents also play, although the distribution of rodent play is quite heterogeneous. Those rodents who do play tend to be social, and social play is the most commonly observed form of rodent play. Prairie dog adults facilitate social play with juveniles, and beavers “dance” together in their aquatic environment (Burghardt 2005). Rough-and-tumble social play is prominent in rat development, as juvenile rats attempt to gently bite their play partner on the neck, while that partner employs a variety of defensive tactics (Pellis and Iwaniuk 1999).

All canid species also play. Domesticated dogs are well-studied and represent an interesting case because they maintain strong social bonds with other dogs and with humans (Bekoff and Pierce 2009). The coevolution of humans and dogs may explain why domesticated dogs play more than their wild relatives: humans appear to have selected for neotenuous traits that may extend juvenile behaviors into adulthood (Bradshaw et al. 2015). Dogs will run, jump, and manipulate

objects in solitary play but are more likely to engage in a diversity of social play. Dogs play together through games of chase, play-fights, and mock sexual mounting (often in sex-reversed configurations). Dogs also enjoy social object play: “fetch” and “tug-of-war” are commonly played with humans, and dogs show increased interest in objects that other dogs or humans are manipulating (Bradshaw et al. 2015). The dog’s enthusiasm for social object play has been exploited by breeders to create “sporting dogs” that will retrieve the quarry of human hunters (Sommerville et al. 2017).

Rules of the game: Social play is common among mammals, but there is some debate as to whether there are any universal features of mammalian social play. Animals playing socially may employ “play signals” that help their partners to differentiate between play and aggression. Bekoff and Pierce (2009) have suggested that these signals are part of a larger system of social rules that represent a definable animal morality. For example, individuals from various canid species appear to observe the following rules:

1. Signal that you want to play
2. Employ real skills, but keep them in check
3. Reverse roles
4. Self-handicap
5. Apologize if you break the rules
6. Forgive rare transgressions

Individuals who consistently break these rules are more likely to be socially ostracized, suggesting that canid play exists at least in part as a means of assessing potential social partners. Bekoff and Pierce (2009) emphasize that the rules of what’s allowed in play may vary from species to species but that these general rules for playing are shared among many species that play socially.

Who plays, and when?: Although there is increased appreciation and understanding of play behavior that occurs in adulthood, the vast majority of animal play occurs in juveniles (Burghardt 2014), a fact that strengthens the connection between development and play. Although there

are no universal rules governing which sex plays or how, numerous studies have shown that sex matters in how individuals play; some studies have even demonstrated the different benefits that each sex realizes from playing (e.g., Dallaire and Mason 2017). In general, larger-brained mammal species tend to display more complex play behavior, although this correlation is stronger at higher taxonomic levels of comparison and may not distinguish more playful from less playful species within a clade (Iwaniuk et al. 2001).

Divergent, parallel, and convergent evolution of play: There are a great number of play behaviors across the animal kingdom that resembles each other in form, often sharing a common discernable function. How did evolutionary processes produce these similar behaviors? One possibility is that a common ancestor evolved a particular play behavior, passing this behavior along to the many species that have since evolved. While this divergent explanation for animal play may apply to the very recent evolution of particular play behaviors in fine-scale taxonomic groups; it is clear that divergent evolution cannot explain the heterogeneous distribution of play behaviors across the tree of life. That the most prolific animal players are corvids, parrots, great apes, and dolphins demonstrates that some combination of convergent and parallel evolution must be responsible for the diversity of play we can observe (Osvath et al. 2014).

Distinguishing parallel from convergent evolution is difficult in general and may be particularly difficult for the various forms of play behavior. Parallel evolution suggests that evolved characteristics in a common ancestor served as a precursor trait that was subsequently similarly modified to produce similar play behaviors. Sociability may serve as such a precursor in many species, with social play evolving independently in related lineages but based upon shared foundational social interactions. The alternative is that play evolved convergently, with play behaviors evolving completely independent of each other, presumably due to similar environmental demands. Because play behaviors do not fossilize, it is very difficult to find evidence to untangle the

subtle differences in pattern produced by convergent and parallel evolution (Burghardt 2005).

Phylogenies of play: One way to determine how play has evolved is to place different kinds of play behaviors on the tree of life, looking for patterns that would be indicative of convergent, parallel, or divergent evolution. Where play is less common, the power of convergent evolution to independently produce play behavior in disparate lineages is clear. If spiders and octopuses are the only invertebrates yet known to play, it is highly unlikely that these behaviors were inherited from a common ancestor (divergent evolution) or even emerged from the independent modification of traits inherited from a common ancestor (parallel evolution). Interestingly, in birds it also appears that the two major taxa that are the most prolific social players – corvids and parrots – are most likely to have independently evolved their similar forms of social play, as both have many closer relatives that do not play socially (Diamond and Bond 2003).

While octopuses, corvids, and parrots may have each evolved play independently *as lineages*, play is common among species within each of these clades, suggesting that divergent evolution may explain the distribution of play at lower taxonomic levels. The most compelling case for divergent evolution of play occurs in particular mammal lineages. All primate species and all canid species play, suggesting that the common ancestor of each of these clades displayed some form of play behavior. Play is also sufficiently common among placental mammals (Burghardt 2005) that it is reasonable to surmise that the common ancestor of all mammals may have displayed play behavior, although the finding that brain size correlates more strongly with play between rather than within clades suggests a role for parallel evolution of mammalian play (Iwaniuk et al. 2001). A study of play among the muroid rodents revealed that neither divergent nor convergent evolution provided a satisfactory explanation of the heterogeneous level of play among species in the clade, suggesting a role for parallel evolution of play or loss of play by some species in the clade (Pellis and Iwaniuk 1999).

Evolution of Play in Humans

Our interest in the play of other animals likely stems from our desire to understand our own very playful nature. Human play has many products that can be readily observed in both small-scale and large-scale societies. Musical play and dance is a nearly ubiquitous feature of human societies. Every culture has its own kinds of games and sports. Word play, jokes, and other creative uses of language suggest that words aren't just for functional communication. While art may be a very serious business in particular segments of many human societies, our drive to playfully create appears to be as ancient as the cave paintings of Chauvet or Maros.

Play in human juveniles: Children are prolific players. The incredible diversity of what constitutes a “toy” (and the broad range of target ages for toy designs) underscores the importance of object play to young humans, but kids are also highly adept at turning all manner of found items into play objects. Locomotor-rotational play emerges within the first year of life and is a whole-body experience: infants move their limbs, use their hands to grasp, and explore with their mouths. Playground equipment is designed to meet the play demands of older children for climbing, sliding, swinging by their arms, and moving rhythmically. Children also demonstrate from an early age the importance of mental play to humans, eventually becoming immersed in a world of imaginative play that can be – from their perspective – indistinguishable from experienced reality.

What makes locomotor-rotational, object, and imaginative play in human children all the more fascinating is how often these forms of play are also social. Children love to play games with both adults and other children that involve chasing and mimicking movement. All manner of objects are used to play with others. And imaginative play frequently involves the creation of fantasy worlds and detailed role-play with other children.

Another form of social play in human juveniles is rough-and-tumble play. As with forms of rough-and-tumble play displayed by other

animals, children will initiate bouts of vigorous but also restrained hitting, pushing, and wrestling, with larger children self-handicapping to maintain a playful interaction. Many studies have demonstrated the gendered nature of this sort of play: boys are far more likely than girls to engage in rough-and-tumble play. While many have suggested that these differences emerge from sex differences in hormonal expression, it is very difficult to separate out the effects of cultural expectations on the relative prevalence of rough-and-tumble play in girls and boys. Future work is needed to assess how gender expectations and biological sex interact developmentally to produce rough-and-tumble play.

All of the forms of juvenile play outlined above can be performed voluntarily and spontaneously; that is to say children are avid devotees of “free play.” But adults also create “structured play” opportunities for juveniles in the form of sports, games (including those hosted on digital devices), and educational activities. Understanding how self- and other-directed forms play differ in their pattern, purpose, and product would further illuminate the role of play in child development, an especially important area of research for societies in which structured play is rapidly displacing opportunities for free play.

Developmental role of play: Play is an essential component of normal human development. Children are playful from an early age; some have suggested that the rolling, punching, and kicking that occur in utero are the first forms of play to emerge (Brown 2009). A few months following birth, human infants begin a process called attunement, an interactive form of play that both strengthens the parent-offspring bond and builds cognitive skills. In their first year, infants also engage in a wide variety of locomotor-rotational play, allowing them to develop the physical coordination, strength, and balance required to begin walking upright. Objects also play an important role in early childhood, as manipulating various components of the encountered environment fosters understanding of physical properties.

A major transition from infancy into early and middle childhood occurs when children move

from playing strictly with adults or older children to playing socially with their peers. While locomotor play and object play still allow for development of physical aptitudes and understanding, childhood shifts dramatically toward fostering an understanding of how to interact with other individuals. Children’s social play can be seen as a way of building two fundamental understandings, a general awareness of how other humans respond emotionally to various kinds of interactions and a more specific awareness of the cultural rules that govern their particular society. The cultures in which children develop vary dramatically, but the role of social play in familiarizing children with the norms of those cultures is invariant.

Adolescence is a period of development with radically different meaning in different human societies. In some societies – particularly smaller-scale subsistence societies – adolescence may be a time in which children assume adult roles (this is especially true of girls). In large-scale societies that require huge amounts of learning in order to attain sociocultural maturity, functional adolescence may extend well beyond the attainment of physical and reproductive maturity. While adolescence varies in timing and duration, it does have some common features across cultures. There are shifts in social play from modes that emphasize group dynamics (such as friendship alliances) to modes that emphasize courting and mating behaviors. It could be argued that where “dating” behavior occurs, adolescents are essentially playing at mate selection and pair bonding in preparation for adulthood. Another key aspect of play in adolescent development relates to experimentation with ideas outside of the family: adolescents become open to new and foreign experiences that have the potential to dramatically broaden their cultural repertoire.

Humans maintain juvenile characteristics for a very large fraction of our overall lifetime. Long periods of childhood and adolescence allow for the advanced development of a variety of physical skills (such as throwing, chasing, running, and fighting) that may have been crucial to the survival of our ancestors. This extended maturation process also increases our ability to learn culturally and may account for our success not only

relative to other primates but also relative to other (now-extinct) hominin species (Nowell 2016). Play is a very effective means by which the long developmental period of human juveniles can be leveraged to maximize behavioral plasticity in relation to a variable environment (Pellegrini 2009).

Play in human adults: The degree to which human adults play is a matter of some debate, as many forms of adult play behavior are intertwined with rigid rules, competition, and social/sexual signaling. Still, some have argued that adult play is a key expression of personality (Brown 2009). Humans are a species capable of lifelong learning, which means that some forms of play could continue to serve the same developmental roles that dominate childhood and adolescence. The role of play in adult tinkering, experimenting, and discovery is well-studied (Bateson 2014), but other play-like behaviors displayed by adults merit further investigation aimed at determining if adults frequently use play in ways that are analogous to the play of children and adolescents.

Many functional roles of human play: Play behavior serves many functional roles in humans. Some of these functions are directly analogous to the functional roles of play in other animals. A young child climbing on a playground structure is developing locomotor skills and potentially training for the unexpected. Humans playing around with tools to make things or trying out various sports are assessing their physical and cognitive capabilities. Forms of social play ranging from dancing to board games to competitive sports all open up the opportunity to assess the reliability and capabilities of potential social partners. A child playing by the rules of a recess kickball game is learning both social norms for fair play and how to cooperate with classmates.

Clearly there is a continuum between the play of other animals and human play, but the functional role of play in humans appears to be different in both extent and kind. Self-assessment provides one example of an “extended function” of human play. Whereas other animals may use self-assessment to determine what prey are profitable to pursue or to what degree they stand a chance in direct forms of sexual competition,

humans actually use play to self-assess and decide what skills to work on for a lifetime. This decision may not be conscious: we find playing at things that bring us success to be more rewarding, which means that we are more likely to pursue and practice those activities which we experience as “fun.” Studies have demonstrated the level of mastery that can emerge from this kind of autotelic play behavior. For example, rugby players are dramatically better at distinguishing between deceptive and honest body movement signals.

The extent of human social play also exceeds that of other animals. This extension of social play could be a reflection of the degree to which humans rely on cooperation with nonrelatives. Other animals may use play to choose allies from within a small social group, but human play forms such as joking, dancing, game playing, sports, and playful conversation are used to create an extensive network of friends that engage in mutual aid. Play’s potential to foster social cohesion may have reached its apex in humans.

Another clear extension of human play relates to when humans play throughout their life histories. While juveniles may play differently than adults, humans tend to play in multiple ways throughout their lives. Play can be used to develop new skills at any age, and humans stay motivated to play throughout adulthood and even as they senesce. While physical forms of play may decrease in frequency as humans age, other forms of play – such as language play or creative play – may be maintained or become more frequent. While most play by adults in other animals is directed at juveniles (and thus may be related to “parenting for play”), human adults also engage in extensive play with other adults.

In nonhuman animals and in smaller-scale human societies, play is generally not needed in order to “keep in shape”: the day-to-day activities required to meet basic needs maintain physical fitness. Humans have clearly evolved a “use it or lose it” physiology that adjusts both musculature and cardiopulmonary capacity to whatever level of physical activity has been recently undertaken. In large-scale industrialized societies, meeting basic needs through various economic exchanges often does not require much physical exertion. In

these societies, play has taken on a new role as a means of maintaining physical fitness. While not all forms of human exercise is playful – for most people, running on a treadmill is work! – many forms of play have assumed a role in producing optimal health outcomes.

Perhaps the most distinctive function of play in humans is our use of mental play (Burghardt 2005). Humans have a strong ability to play entirely in our own minds. One such form of play involves simulation of fantasy worlds via mental rehearsal or reenactment, which allows us to both process past events (Dallaire et al. 2017) and to plan and prepare for future events. In this sense, fantasy play is a kind of time travel, allowing us to learn from things that have already happened and to anticipate events that haven't yet happened. Mental play can also be used to come up with new cultural ideas. In humans, imagination and improvisation are closely related to problem-solving and innovation; our creativity relies in large part on our playfulness (Bateson 2014). We like to play with ideas that we have learned from others, tweaking and modifying existing culture in a way that allows for collective innovation through cumulative culture. It is hard to know if other animals engage in mental play, and there are a few other species (such as ravens) that appear to come up with novel solutions to problems via playful behavior. But a consideration of the abundant cultural products of human mental play makes it clear that if we are not the only mental players, we certainly rely on mental play to an unprecedented extent.

One interesting aspect of human play behaviors is that many lead to what would be best categorized as performance. In animals, the difference between play and performance is generally pretty clear: playing at mock-mating happens at a different developmental stage and in a different context than real mating, and there is a distinct behavioral difference between play-fighting and agonistic fighting. But many human behaviors that relate to play blur the line between play behaviors with immediate and delayed functions. A musician may be “playing” music (and certainly a lot of music-making is initially purposeless), but this playing could be a display with the

potential to attract a mate. Is the cultural importance of music the result of selection for playful experimentation or for play as a product of sexual selection? The fluidity of human play makes answering such a question difficult. An athlete may be playing a particular team sport, but this playing could be a display with the potential to cement cooperative relationships with other players once they leave the field of play. The manner in which play is integrated into everyday human life (and not just among children) makes it difficult to distinguish when the potential benefits of human play are manifested.

The Playful Mind: Implications for Human Well-Being

That play could be an adaptive behavior has important implications for human health and well-being. If play is a human adaptation that empowers complex learning, mental preparation, physical fitness, social bonding and cooperation, and discovery and creation, then maintaining access to beneficial opportunities to play is a serious health issue.

Play as a cause and correlate of mental health: There has been a long debate in the animal behavior and psychology literature about whether or not play can be used as either indicative of welfare or as a means to achieving optimal welfare. Many studies have shown that play can improve the welfare of both animals (e.g., Held and Špinka 2011; Bateson 2014) and humans (Landreth 2002). A more subtle question is whether the presence or absence of play behavior can be used to assess welfare. While there is compelling evidence that depression of play activity can be used as an indicator of poor welfare, the opposite is not true: an abundance of play does not necessarily indicate positive mental or physical health (Dallaire et al. 2017). This is particularly true in humans, who may use forms of solitary play, such as reenactment, to deal with trauma. An exciting possibility is that shifts in the mode of play – such as from social to solitary – might be used to diagnose the affective state and overall welfare of human patients.

Zone of proximal development and productive forms of play: Russian psychiatrist and researcher Lev S. Vygotsky was the first to conceptualize the idea of a *zone of proximal development* (ZPD). The ZPD was based on the idea that in order to gain new understandings, a learner must be challenged beyond their current level of competency but not be overwhelmed by a challenge far beyond their capabilities. Play often appears to occur in environments that seem to create a ZPD: we don't enjoy playing in environments that present too few challenges because they are boring, but we also don't enjoy playing in environments that are overly challenging because they are unduly stressful. Vygotsky saw play as the ideal means by which children productively enter the ZPD and orchestrate their own learning. The kind of play that Vygotsky's research demonstrated was key to learning is observed less in children today than those of past generations, suggesting a unique challenge to modern-day educators: how do we restore play as an optimal means for enabling learners to enter their ZPD (Bodrova and Leong 2015)?

Changes in the role of play in large-scale societies: Large-scale, industrialized societies have dramatically changed what we play, how we play, and how much we play at different points in our life histories. If a "relaxed field" is required to stimulate play behavior, industrialized societies certainly increase the abundance of such environments: compared to our ancestors, a much larger fraction of people are free from daily concerns about food availability or personal safety. An overall increase in leisure time also enables many people more time in which to play in this relaxed field. In addition to creating an environment that is conducive to play, large-scale societies tend to require more extensive cultural learning; this requirement for extended and sometimes lifelong learning can functionally extend adolescence (a time of intense play) and make play important throughout adulthood.

Ironically, despite the unprecedented resource availability and safety of our time, certain forms of play appear to be in decline, at least in large-scale/industrial societies. For example, in the latter half of the twentieth century, the time children

spend playing – in particular outdoor play not directed by adults – has dramatically declined. This decline in play is associated with increased levels of anxiety, depression, and narcissism in adolescents and young adults, leading some to suggest that this shift in the abundance and pattern of childhood play is a major mental health issue (Gray 2011). Despite evidence to the contrary, parental perception of dangers external to the home seem to be a major driver of this change in play behavior, marking a major shift in the culture of childhood play.

Other forms of cultural evolution have also dramatically changed how we play. The Internet creates the potential for social interaction that differs from our ancestral social environments in both extent and kind, opening up unprecedented opportunities for social play. Virtual online worlds become not just additional spaces in which to play: they create entirely new play environments. Industrialized societies produce novel objects that foster totally new forms of play (e.g., skateboards, mountain bikes, skis, sailboats, and all manner of balls). Play has also been highly commercialized, opening up the possibility that forms of play behavior may be influenced not just by our evolved propensities to play but also by marketing.

Play has also infiltrated the world of design, where creative industries have strived to harness the power of play to create novel ideas and motivate extraordinary human effort. Companies provide their employees with break spaces that encourage play and try to incorporate play into the way that they address business challenges (Brown 2009). Although an understanding of our playful nature has impacted some workplaces, it would be mistaken to overestimate the extent of this impact: work environments that embrace play represent a tiny fraction of the overall global workplace and tend to exist in the sector of industries that rely on the creation of new products or other forms of novel design.

Play as a privilege: Although many people have been enabled to play more frequently and further into adulthood, this condition is far from universal. Inequities within and between societies create a dynamic in which some people live under

ideal conditions for play and others are deprived of the opportunity to play. This deprivation applies to children as well as adults: kids who are undernourished or have to work are less likely to spend their time playing (Bateson 2014). Acknowledging that play is currently a privilege but is also an evolved developmental need, the United Nations issued a proclamation establishing play and a “universal and inalienable right of childhood” (Landreth 2002).

Mismatch theory and modern play: Human play behaviors evolved in a very different environment than the one that most people experience today. Our play emerged in smaller social groups of hunter-gatherers who interacted with far fewer individuals and far fewer objects (especially human-made cultural objects) during a human lifetime. Thanks to the prolific cultural evolution produced by modern industrialized societies, we now have access to far more objects to play with, environments to navigate, and people with whom to interact. The cultural evolution that creates these new environments dramatically outpaces human genetic evolution, setting up the potential for play behaviors that are “mismatched” to our current environment.

One potential outcome of this mismatch is various forms of play-related addictions. Perhaps the most obvious play addictions are to electronic games, particularly those which combine vivid forms of fantasy play with real-time social interactions with a limitless supply of play partners (Brown 2009). Such addictions may emerge because opportunities for free play are being supplanted by more structured forms of play. Many forms of gambling may also exploit playful human curiosity, leading some people to become compulsive gamblers. Such addictions can, ironically, pull people away from healthy forms of play that are key to maintaining physical and mental health.

Another potential outcome of this mismatch is play that is excessively risky. Again, it is the use of new cultural technologies that may shift normal play behavior into maladaptive territory. Online dating apps may turn normal sexual play into a compulsion. Access to various kinds of motor vehicles produces new and dangerous forms of

locomotor play that can be a major source of mortality among young adults. Certain forms of “new play” enabled by both novel material culture and novel cultural ideas (such as free solo rock climbing, big wave surfing, and BASE wingsuit jumping) attract some people to play under extraordinarily risky conditions.

Understanding how and why humans evolved to play can enable us to better design modern societies – and forms of play within those societies – that create fewer of these pathologies and extreme risks.

Conclusion

Play is a rare but remarkable animal behavior that in some cases is an adaptation to the challenges of a dynamic social and ecological environment. The role of play is most prevalent in juveniles, with many of the benefits of play being manifested through developmental processes, but play can also serve a function in adulthood. While the most complex forms of play are found in the mammalian lineage, the prevalence of play in other animal groups suggests both its broad adaptive utility and the role of play in the success of many lineages of the animal kingdom.

The delayed nature of play benefits, combined with the difficulties of comprehensively observing any complex animal behavior in a natural setting, makes studying play from an evolutionary perspective a challenge. There is still much scientific work to be done to unravel the functions of play in both humans and nonhuman animals and to illuminate how play evolved, but substantial progress has been made over the last two decades. A major innovation in the field has been the positing of clear, distinct hypotheses that make contrasting predictions about what we should observe in animals that display play behavior.

Humans are a particularly playful species, with play behavior enabling much of the learning that occurs during humans’ extended developmental period. The persistence of play well into adulthood suggests that human neurological development continues well past attainment of sexual maturity and that in some ways humans may be

continually developing. Understanding humans as a species that evolved to develop via play can enable us to design better educational systems, improve workplace creativity, and foster better mental and physical health outcomes.

Evolution of Punishment

Edward Dutton¹ and Guy Madison²

¹Ulster Institute for Social Research,
London, UK

²Umeå University, Umeå, Sweden

Synonyms

Castigation; Chastisement; Correction; Discipline

Definition

The infliction of a penalty in retribution for an offence.

Introduction

Punishment is a human universal, and it is also found among many social animals. It applies to all social relationships but may take on different forms and fulfill different functions depending on whether it is applied to children, inferiors, or peers, for example. Here, we consider the adaptive value of punishment, and why specific kinds of punishment may have evolved.

Competing theories attempt to explain the cross-cultural propensity to punish. Punishment may confer reduced fitness, such as when the punishment reduces the social status, or the somatic health of the recipient, such that it negatively affects the recipient's number of offspring. In general, punishment is imposed because the recipient will not cooperate; he behaves in a manner that is costly to the punisher but beneficial, at least in the short term, to the recipient. The question is then how reducing the fitness of some members of a group can elevate the fitness of the group, such that a propensity to punish remains.

Evolution of Psychological Faculties

► Alfred Russel Wallace (1858)

Theories of the Evolution of Punishment

One school of thought holds that the key purpose of punishment is to prevent the

repetition of the punished form of behavior. For example, more experienced individuals can share their knowledge by punishing less experienced individuals (such as children) for performing behaviors that are dangerous to themselves or to the group. Punished behaviors would thus include playing near a cliff or a water-front, so that a moment's loss of control leads to injury or drowning, or it could be chattering and shouting in the vicinity of competing bands, exposing one's own group to ambush. However, this does not account for the propensity, found in many societies, to punish overly-severely, unfairly, or with no obvious benefit for the recipient. Another school holds that punishment generally involves a reaction to some form of cheating or non-cooperation. Severe punishment can be explained by the way in which it deters free-riders and cheats who undermine the cohesion and adaptive operation of the group to which they belong (see Nakao and Machery 2012). Specifically, punishment behaviors would be naturally selected for to the extent that the fitness elevation they entail outweighs the fitness reduction which they cause. To this elevation must be counted long-term adaptive effects of cooperation and rule-following, behaviors that tend to be adaptive both in individuals and among groups when in conflict with other groups (see Dutton and Woodley of Menie 2018). Capital punishment is an extreme example in that there is no possible benefit to the recipient, so it must thus be compensated for by a substantial benefit for the group. Benefit would accrue, for example, when an individual's destructive behavior is due to genetic influence, which is thereby decreased in the gene pool through his execution. Examples include psychopathy, mental instability, and other anti-social behavioral tendencies that entail betrayal, violence, and internal conflict (Dutton and Madison 2018).

In these situations, behavior modification of the recipient is of no direct benefit to either party, in which case it has been argued that punishment may have evolved, in part, because of the benefits accrued by the one who punishes. If the punishment consists of the withdrawal

of some form of aid (this being a self-imposed cost) that constitutes a benefit to the punisher, especially if it means that the recipient becomes less able to harm him. More generally, depending on the severity of the punishment, it means that the punisher may end up with more descendants than the recipient (Nakao and Machery 2012). When including this macro-perspective of punishment, behavior modification is merely one aspect of its evolution. Nevertheless, many forms of punishment, such as the spanking of children by parents, likely aim to elevate the genetic fitness of the recipient. Indeed, a parent has conceivably no interest in reducing the fitness of its offspring other than in extreme circumstances, such when a young woman in a very difficult labor has to choose between her own life and that of her baby. Should she survive she would be able to have many more children. Accordingly, there may be several strands in that a propensity to punish has evolved because those who punish are more likely to survive, those who have been punished for key violations are more likely to survive and so pass on the inclination to punish, and groups who punish are also more likely to survive.

The Evolution of Spanking

Some particular characteristics of punishment practises may be informative with regard to punishment's evolution and adaptive function. The dominant forms of punishment vary between cultures. In many tribal societies, those who are physically punished are beaten up until they plead for mercy (e.g., Freeman 1983). However, the propensity to beat the buttocks, a.k.a. spanking, appears to have developed independently in both Europe and Northeast Asia, testified to by evidence of the ancientness of the practice in both contexts. Children were beaten on the bare buttocks in ancient Pompeii as well as in Early Modern England, where it was applied to wives, children, errant servants, and certain kinds of criminals (McCoy and Keen 2013). Spanking has developed independently in quite unrelated developed cultures, such as those of the Far East,

in which flogging men and boys to the point of bleeding on the bare buttocks is documented from sixteenth century China (McCoy and Keen 2013).

Due to the similarity in procedure in two independent cultures, spanking is unlikely to be a “fluke” development, and it has thus been suggested that it may be a result of evolutionary processes. Importantly, spanking is associated with positive life outcomes for the recipient when this violence is ritualistic, structured, controlled, not overly severe, and administered by a parent or guardian who is predictable and otherwise loving, controlling for factors such as socioeconomic status (Larzelere 2000). Indeed, when the children in studies were from groups which tend to have poor impulse control and low agreeableness then the outcome was positive even if the corporal punishment was extremely severe, as long as it was structured and predictable (Lansford et al. 2009). When imposing genetic controls, corporal punishment only led to poor life outcomes if comprised of random violence, such as punching and kicking (Lynch et al. 2006). Morris (1969) suggests that spanking may have a common evolutionary root in a submissive social behavior observed in chimpanzees. If a subordinate male gets into a situation of conflict with a dominant chimp, he will instinctively present his posterior to the dominant chimp. The dominant chimp will then briefly mount him, which defuses the situation. These kinds of behaviors seem to increase the fitness of the lower-status individual. Many mammals – with dogs offering their necks or being mounted by same-sex superiors as the prime example – perform acts of submissiveness, humiliation, and ritualized violence in substitution for real violence. Likewise, mimicking femininity may function to pre-empt violence by changing the role of the adversary from a male to be competed with into a female to be mated with if one wishes. Both dominating and submissive behaviors are likely reinforced by regulation of serotonin, for example, extending them in time. In effect, inflicting serious injury is avoided while the teacher, parent, or other authoritative agent can still maintain a trusting

relationship. In addition, undergoing a ritual which involves submissiveness, degradation, and pain, but also control and predictability, may foster the recipient’s character to deal with a milieu that is harsh and yet highly predictable. This would, therefore, be of particular benefit in the ecologies of Europe and Northeast Asia that have historically been particularly “harsh yet predictable” (Dutton and Woodley of Menie 2018).

Evolution of Less Violent Punishment

There are many ways in which people can be punished, ranging from slighting, verbal abuse, and threatening, to shouting, slapping, and varying degrees of physical violence, including execution (Clark 2007). It has accordingly been suggested that punishment has tended to take a violent form because of evolutionary reasons. For example, Frost and Harpending (2015) have shown that the widespread execution of criminals in Medieval and Early Modern Europe had the effect of removing from the gene pool those with particularly low Conscientiousness and Agreeableness, leading to a more cooperative society, better adapted to triumph over rival societies and over the elements. Dutton and Madison (2018) extended this argument to intelligence and religiousness, both of which they show to be associated with in-group cooperation. From the Early Modern Period onward, when Western societies were nevertheless still under preindustrial conditions of Darwinian selection, punishments became decreasingly violent and bloodthirsty (Clark 2007). In terms of the evolution of punishment, this may be because intelligence was increasing every generation up until the Industrial Revolution, due to the association between intelligence and wealth and the concomitant positive association between wealth and fertility, as shown using proxies from Clark’s research (Dutton and Woodley of Menie 2018). Clark’s research shows, for example, that the richer 50% of English testators in the seventeenth century had almost double the number of surviving

children than the poorer 50%. Dutton and Woodley of Menie aver that as intelligence is associated with empathy, punishments began to become less violent as people became more empathetic, although a period of particular environmental harshness would have lessened this supposed evolutionary trend. They accordingly conclude that rising intelligence, combined with decreasing environmental harshness and decreasing stress, helps to explain a decreased propensity towards violent punishment. As such, punishment has been indirectly affected by selection for a certain trait – intelligence – in humans.

Definition

Evolution of reciprocal altruism studies the evolutionary basis of cooperation within evolutionary agents (here special focus on *Homo sapiens*)

Introduction

Humans (*Homo sapiens*) are arguably the most cooperative primates (Smith 2003). We display unique characteristics such as cooperating on tasks with non-kin members in large groups across cultures (Tomasello et al. 2005). Human cooperation studies have gathered wide interest from psychologists, evolutionary anthropologists, behavioral ecologists, economists, etc. Humans, therefore, make an interesting case study for reciprocal altruism. In the face of theoretical puzzles around reciprocal altruism, the scale of human cooperative societies seems particularly defiant.

Cooperation in Humans

One common explanation for this seemingly abnormal scale of cooperation was the existence of social norms and the ability to understand others' intentions (Fehr and Fischbacher 2004; Tomasello et al. 2005). Norm-based cooperative theories suggested that players who were aware of social normative expectations would act cooperatively in order to fulfil social norms. This was

corroborated by several studies in behavioral game theory showing that human players routinely violated selfish rational expectations and chose to consistently cooperate (across demographics) even at a cost to themselves (Camerer 2003). This norm-based reasoning seemingly presented a cross-cultural advantage to humans in building large successful societies.

However, a large cross-cultural study by Henrich et al. (2001) revealed that when studied in behavioral game theoretic experiments, human players from different cultures exhibited peculiar but remarkably variant patterns. This finding forced a reexamination of the social norm-based explanation for human cooperative systems. If players in culture A consistently shared 50 % of their endowment with other players in an ultimatum game, why did players from culture B share close to zero? This would seem to violate the assumption of common social norms shared across human societies, which contribute to the widespread cooperation. The apparent violation of social norms deserves some attention.

Tomasello et al. (2005) argue for the existence of particular and exceptional abilities such as theory of mind and “shared intentionality” is likely to be a reason humans are remarkable cooperators and altruists. If true, these abilities could function to inform the other player’s expectations and reactions, which in turn would allow their opponents to make a variety of decisions in behavioral games. For instance, a player in culture A could be aware that their opponent who is from their own culture would think it is normal for a proposer to split the endowment unevenly, whereas in a different culture, 50 % sharing could be the norm. The combination of insights from Tomasello’s and Henrich’s work reveals that rather than being a standard “fairness” based social structure, player reasoning could operate by anticipating other person’s perception of their actions.

Conclusion

The inclusion of theory of mind and shared intentionality measurements in cross-cultural studies is likely to be able to test this concern and provide

additional theoretical power to behavioral game theoretic studies.

²Psychology Department, University of Southampton, Southampton, UK

Synonyms

Consciousness; Metacognition; Self-awareness; Self-consciousness; Self-reflection; Self-thought

Definition

The term “the self” is broad. It can encompass: (1) knowledge that one is separate and distinct from others, (2) knowledge about the degree to which one is consistent over time, (3) knowledge about how one is a causal agent in the world, (4) information about the attributes (e.g., appearance, personality traits, habits) that one possesses, (5) information about one’s goals or motives as well as plans to execute them, (6) knowledge about one’s significant roles and relationships, (7) the result of judgments made about oneself, and (8) feelings or emotions that one experiences in response to self-thought.

Introduction

People experience “a sense of self.” This may include ideas about how they look, who they are now, how they were in the past, and what they have done in the past. They have the experience that *they* (not an outside agency) do things, and that *they* (and not an outside agency) are the source of their own thoughts. Scholars have long been captivated by the study of the origins, functions, and functioning of this sense of self, and the long and intensive study of this topic has generated a voluminous empirical and theoretical literature (for a sampling, see Leary and Tangney 2012). Indeed, self-awareness has been called

“arguably the most fundamental issue in psychology . . .” (Rochat 2003).

One proposition in the self literature is that the mental experiences linked to the self have emerged via evolution (Sedikides et al. 2006). This evolutionary perspective reflects the following assumptions: (1) some organism’s psychological characteristics are rooted in genetics; (2) these genetically influenced psychological characteristics will spontaneously vary across organisms in a population; (3) some characteristics are a better fit to an organism’s environment than are others; (4) those individuals who possess the advantageous psychological characteristics will be especially effective in the organism’s environment, which will contribute to the organism being particularly successful in reproductive activities; (5) reproductive success will lead to a subsequent species increase in the extent to which the advantageous characteristics occur in the population; and (6) this shift in characteristics will be accompanied by continuing variability among individuals in the population (such variability is a precondition for evolution).

These assumptions have several implications for the patterns of data that one should observe when searching for evidence related to the self. One implication is that the human experiences of self are linked to physical elements of the body (e.g., genetics, brain structure, brain function). A second implication is that the current human experience of the self may not match the experience of the self in early species members (or in earlier hominid species), but may have changed over time. A third implication of an evolutionary approach to the emergence of the human self is that at least some self-like capabilities may be shared with nonhuman species. A fourth implication is that the self should be adaptively functional. This chapter briefly elaborates on these implications and presents evidence.

None of the relevant sources of evidence is conclusive on its own. For example, although high current trait functionality is consistent with an evolutionary perspective, it does not constitute sufficient evidence for it. A trait can be functional in a given environment, but can still be solely derived from experience (e.g., pathogen

exposure). Moreover, even when rooted in natural selection, trait functionality can shift across the evolutionary timescale. A trait may have initially evolved in response to a given set of environmental selection pressures, but, as time progresses, selection of the trait might be governed by a set of environmental pressures that are entirely different from the ones that were originally responsible for its selection.

Another potential concern is that traits exhibited by a species are simply side effects that emerge from the process of selection, but they are not themselves a focus of those selection pressures. For example, evolution may have worked to promote the production of neurons that are densely interconnected with other neurons. If one collects enough neurons, if the neurons are of the correct type, and if the neurons are interconnected in the right way, then the sense of self may spontaneously emerge from the resulting system. Moreover, this sense of self may be functional. Thus, even if humans can be shown to have a biologically influenced sense of self that enhances functioning, it may not be true that evolution specifically selected individuals who have a sense of self.

However, although each source of evidence pertaining to the evolutionary origins of the human self may not be definitive on its own, it is also the case that the available evidentiary sources strongly converge, favoring the evolutionary hypothesis. We illustrate this point by highlighting some of the converging evidence.

Getting a Grasp on the Self

Exactly what is this “self” that has been the object of so much theoretical speculation and empirical attention? One answer comes from a developmental perspective, which posits that the self develops gradually through a succession of behaviors. The ability to monitor and reflect on these behaviors, otherwise known as metacognition, is thought to be an indicator that an individual possesses a self-concept. For example, using reactions to a commonly used test for the self-concept, the

“mirror test” (e.g., how one responds to one’s own reflection in a mirror), Rochat (2003) proposed five levels of self-awareness. These are as follows:

Level 0: Confusion. At this level, there is no self-awareness. The person is unaware of any mirror reflection or the mirror itself. They seem to perceive the mirror as an extension of their environment.

Level 1: Differentiation. The individual realizes the mirror is able to reflect things. They understand that what is in the mirror is different from what is surrounding them. They differentiate between their own movement in the mirror and the movement of the surrounding environment.

Level 2: Situation. The individual can link the movements in the mirror to their body perceptions. This is the beginning of the realization that what is visualized in the mirror is special to the self.

Level 3: Identification. The individual can now see that what’s in the mirror is not another person but actually him/herself. Thus, at this stage, instead of referring to the mirror while referring to him/herself, the individual refers to him/herself while looking in the mirror.

Level 4: Permanence. Once the individual reaches this level, they can identify the self beyond the present mirror imagery. The individual now experiences a “permanent self,” and this is accompanied by the ability to identify the self in previous pictures as looking different or younger.

Level 5: Self-consciousness or “meta” self-awareness. Here, thinking is accompanied by the realization that the image in the mirror can be seen from a third person’s view, and not just the first person perspective. The individual begins to understand that they can be “in the mind of others.” For example, the individual may understand how they are seen by others.

However, such conceptions may focus unduly on metacognitions and self-reflection. The more researchers consider the activities and functions that are linked to the self, the more complex they

find the answer to the question “what is the self” to be. For example, Klein and Lax (2010) noted seven types of self-knowledge.

1. Episodic memories of one’s life events.
2. Semantic summary representations of one’s personality traits.
3. Semantic knowledge of facts about one’s life.
4. An experience of continuity through time: The “I” experienced now is connected to the “I” experienced at previous time points.
5. A sense of personal agency and ownership: The belief or experience that “I” (agency) am the cause of “my own” (ownership) thoughts and actions.
6. The ability to self-reflect: Forming meta-representations where the agent is the self and where the agent makes inferences on the basis of those representations.
7. The physical self: Represent and recognizing (e.g., in mirrors, photographs) one’s body.

Some theorists have attempted to find an underlying organization to these different facets of self-knowledge. For example, one conception (Fingelkurts et al. 2016) suggests that the experiences of self incorporate three main contributors. One provides the first-person perspective and the sense of agency (the witnessing observer); the second provides the experience of self as a localized embodied entity, emotion-related thoughts, and autobiographical memories (representational-emotional agency); the third provides the experience of thinking about oneself, including momentary narrative thoughts (reflective agency). The theoretical conception has the additional advantage of grounding each of these contributors in brain structure and function. The conception suggests that selfhood involves the activation of a default mode network (DMN) that links neural activity in frontal-left, posterior-right, and posterior-left areas of the cerebral cortex. More specifically, the DMN is commonly viewed to include the left and right middle frontal gyri, bilateral frontal medial areas, left and right middle temporal and occipital gyri, and left and right precuneus. These are thought to be active and functionally synchronized during

self-related tasks and when participants engage in self-generated thoughts.

On the Adaptive Functionality of the Self

The study of self-related brain functioning is only one source for the converging evidence pointing to the evolutionary origins of the self. One other clue to the natural selection of a characteristic lies in the characteristic’s functionality. That, if the self is an adaptive trait for a species, a researcher ought to be able to document the ways in which the self is functional to the species. Parker (1997) has made exactly this evolutionarily driven self-functionality argument not only for humans but also for nonhumans, as well. We will consider the nonhuman angle of the self later. For now, we focus on the functionality of the self for humans.

As would be expected from an evolutionary standpoint, there is variability among individuals in terms of their ability to experience a self. Clearly, when considering this variability, some forms of self-related thought are not adaptive for humans. Excessive focus on the self can produce maladaptive thinking and can impair task performance (Pinel and Bosson 2013). Moreover, an excess of “selfness,” manifested in the form of narcissism, can similarly produce negative consequences (Sedikides and Campbell 2017).

However, when viewed from a broad perspective, the evidence also suggest that humans who have a well-formed self do better than those who do not. For example, the ability to experience a self may be diminished in persons with schizophrenic disorder (Molnar-Szakacs and Uddin 2016) and persons with autistic spectrum disorder (Lind 2010; Lyons and Fitzgerald 2013). Similarly, a person who experiences damage to, or an impairment of functioning in, their right hemisphere will sometimes suffer from depersonalization disorder, manifesting an altered, detached, or estranged sense of self (Kober et al. 2005). Moreover, while sometimes able to function adequately, those whose self-related memory (and thus, their sense of self) is diminished because of disease-induced or accident-induced brain damage exhibit impaired functioning in real-world

contexts, including the social and/or occupational functions of daily life.

Theorists argue that this functionality is especially evident in the human social world (e.g., Humphrey 1986). Indeed, it may be the case that only species capable of self-reflection are able to use introspectively based social strategies and to experience socially grounded emotions, such as evaluative embarrassment, pride, shame, and guilt. Thus, reflecting on and understanding one's own behavior allows one to engage in sophisticated and nuanced social behavior. This is especially true when species members have a high degree of interdependence, as do humans. Both cooperation with, and competition against, other species members can be enhanced when one has the ability to reflect on the self and to anticipate one's own behavior as it relates to the behavior of others in various social contexts. Moreover, mental simulations that involve the self may be especially important for optimal selection of long-term goals and a reduction in the likelihood of failure.

Behavioral Evidence and Cognitive Evidence from Nonhuman Species Linking Evolution to the Self

Cross-species comparisons of behavioral characteristics and cognitive characteristics can also provide converging evidence pertaining to the thesis that the self is a product of evolution (Sedikides and Skowronski 1997). Evolution does not create something from nothing – it merely selects from what is already available. Thus, any given biologically based characteristic ought to be present in other species, though perhaps only in rudimentary form.

One such characteristic is self-recognition. It has long been known that chimpanzees are capable of recognizing as “self” their own image in a mirror. Subsequent investigations showed that this capacity is shared among other great apes (bonobos, gorillas, orangutans), and perhaps even among primates such as rhesus monkeys who are not as similar to humans as are the great apes. However, even some nonprimate animals

seem to exhibit this capacity. The list includes dolphins, orcas, and the Eurasian magpie (for a cross-species overview, see Mitchell 2012).

This list may lengthen substantially in the near future. Recent thinking indicates that additional evidence of the presence of the self in nonhuman animals can be obtained by “tuning” self-tests to the species being tested. That is, many studies looking for evidence of animal self-concepts have used “the mirror test.” This test seeks evidence that an animal somehow recognizes an image in a mirror as “them.” The test, however, may not be diagnostic of the presence of a self-concept in animals that rely on nonvisual sensory systems. For example, studies conducted with dogs using olfactory cues instead of visual cues tentatively suggest that dogs may possess a self-concept.

Such cross-species diversity might have emerged because evolution often solves similar environmental problems in similar ways. Thus, if a nonhuman species occupies an environmental niche similar to the niche occupied by the species in the evolutionary line that led to the human species, then nonhuman species might be expected to exhibit characteristics similar to the human species. For example, the hominid line has included relatively large-brained individuals whose food sources were widely dispersed in time and space. Similar descriptions can be applied to elephants and dolphins. Thus, the emergence of “the self” in all these species may not be coincidental but instead may reflect evolutionary convergence.

An additional indication of self-producing evolutionary convergence comes from the observation that many of the species that exhibit self-recognition also tend to be highly social. This observation suggests that self-recognition capacities may enhance individual functionality in a social context. This converges with the view that primate brains are “built to be social.” Via evolution of the capacity for self, nature may have found a way to tune big-brained social organisms so that they be well suited to survival in environments that present difficulties in food procurement.

Pursuing a related line of thought, Hills and Butterfill (2015) proposed behavioral and

biological commonalities between external foraging in space and internal foraging over environments specified by cognitive representations, and they explored the implications of these commonalities for understanding the origins of the self (for similar ideas, see Sedikides and Skowronski 1997). Hills and Butterfill suggest that one of these components is auto-noetic consciousness, a term that refers to the ability to mentally place the self in the past, in the future, or in counterfactual situations. This capability allows one to examine one's own thoughts, a kind of self-consciousness that likely is a contributor to the self-multiplex.

Exploration of whether nonhuman species have auto-noetic consciousness has concentrated on the seeming ability of nonhuman species to experience episodic memories. Episodic memories involve subjective event re-experiencing (including images, sights, smells, and feelings), as well as the knowledge that these events occurred in an earlier time. Lou et al. (2004) reasoned that auto-noetic consciousness emerges via retrieval of episodic memories and that such retrieval affects conscious self-representation. This episodic memory capability would seem to be functional to the self. In the absence of the ability to recall experiences and reflect on them, humans would be stuck in a state of constant awakening, without a past and therefore unable to prepare for the future.

Accumulating evidence suggests that episodic memory (and, by extension, auto-noetic consciousness) may not be unique to humans (but see Klein 2014). For example, research results show that animals can act as if they remember time. This tendency can be seen in species that are, in evolutionary terms, close to humans, including chimpanzees and bonobos, baboons, and rhesus monkeys. For example, in one study (Martin-Ordas et al. 2010), preferred perishable food (frozen juice) and less preferred but non-perishable food (grape) were hidden from primate subjects. The subjects could choose one of the foods either after 5 min or 1 h. The frozen juice was still available after 5 min, but melted after 1 h, becoming unobtainable. The primate subjects chose the frozen juice to a significantly greater extent after 5 min and the grape after 1 h,

suggesting that they could remember how the passage of time affected the results of their foraging episodes. Similar findings have been reported for nonprimate species, including nonprimate mammals (rats, meadow voles, Yucatan minipigs, dogs) and birds (pigeons, black-capped chickadees, magpies).

Given these findings, that animal behavior can be sensitive to time is not in much doubt. At issue is whether an animal's ability to use time reflects the presence of an episodic memory system and/or auto-noetic consciousness. Attempts to resolve this conundrum may come from neuroimaging and neuroanatomy studies. Results from such studies indicate that episodic memories in humans depend on the integrity of the hippocampus and related structures. This also seems to be the case for nonhuman species. For example, after encountering a sequence of five odors, the behavior of rats with hippocampal lesions was inconsistent with the idea that they could recall odor order. This insensitivity to order occurred despite the rats acting as if each odor was familiar (Eichenbaum 2013). Additional support comes from studies of monkeys with fornix lesions. Such lesions disrupt the hippocampal system: lesioned monkeys were unable to make accurate recency judgments (Charles et al. 2004). In all, the probable presence of a time-sensitive episodic memory-like system in nonhuman species, as well as in humans, fits with the general thesis that the human self was formed as a result of evolutionary pressures.

One other indicator of the self is a sense of agency over one's actions: the subjective awareness that one is initiating, executing, and controlling one's volitional actions. This sense of agency is sometimes impaired in humans who have a disrupted self, such as those with schizophrenic disorder or autistic disorder (Molnar-Szakacs and Uddin 2016).

Do nonhuman species share this sense of agency? The answer seems to be "yes" (Moore 2016). For example, in one study (Kaneko and Tomonaga 2011), chimpanzees were presented with two cursors on a computer display. One cursor was manipulated by a chimpanzee using a trackball, whereas the other cursor displayed

motion that had been produced previously by the same chimpanzee. Chimpanzees successfully identified that cursor they were able to control. Additional studies showed that at least one chimpanzee could monitor the movement that was theirs in both the temporal dimension and the spatial dimension. Such understanding of agency may also extend beyond the primate line (e.g., to dolphins).

We speculate that this sense of agency may (at least partially) be rooted in the mirror neuron system. Although this system has been implicated in one's ability to mimic others, it also seems to be involved in the monitoring of self-movements, which may contribute to the sense of agency (Maeda et al. 2015). Interestingly, the mirror neuron system may, in evolutionary terms, be relatively old, given that it is shared with other species, such as birds (Prather and Mooney 2015). This may represent another example of how evolution co-opts existing traits. The mirror neuron system, which likely evolved to facilitate social learning, may have been shaped by evolutionary pressure to be a contributor to an individual's sense of self.

For How Long Has the Human Species Possessed a Self?

The possibility that the self (or at least components of the self) can be shared across species suggests that "selfness" (or at least some components of the self) ought to be present in early humans, or even in the hominid species that may have predated humans. Evidence relevant to this point can be examined by looking at the things that the human species have left behind over time.

Using such evidence, early views of the self's emergence in humans noted that evidence of human "selfness" was in place for humans who lived as early as 50,000 years ago (Leary and Buttermore 2003). The evidence for such a date was relatively ample and included the presence of artistic figurines, bow-and-arrow technology, and personal ornamentation. The evidence also indicated that humans were performing ritualized burials. However, recent

artifacts (Hublin et al. 2017) have pushed this "selfness" date back substantially, even to as long as 300,000 years ago. For example, recovered beads, likely used for personal adornment, dated to about 100,000 years ago. Other finds indicate that ochre, a color often associated with bodily adornment, was used by hominid species about 164,000 years ago. Some evidence even suggests that the capacity for self predates the human species: A carving of the head and torso of a woman attributed to *Homo heidelbergensis* has been dated to at least 250,000 years ago.

Evidence Linking Brains, Genes, and the Self

A substantial corpus of research has explored whether self-related thought is linked to specific areas of the brain. Reviews of the work that explores self-related thought (Northoff 2013) lead to clear results. A set of brain regions collectively referred to as the cortical midline structures (CMS) show a special significance in self-related thought. Studies looking at neural activity levels demonstrate that stimuli that are personally relevant (vs. not) to individuals induce higher neural activity in several CMS regions. Such patterns emerged across stimuli, including faces, trait adjectives, movements/actions, memories, and social communication. The implicated CMS regions include the perigenual anterior cingulate cortex (PACC), the ventromedial and dorsomedial prefrontal cortex (VMPFC, DMPFC), the supragenual anterior cingulate cortex (SACC), the posterior cingulate cortex (PCC), and the precuneus.

Interestingly, some of these areas also may be implicated when thinking about others. Such areas include the midline regions, the dorsomedial prefrontal cortex, and the posterior cingulate cortex. This result points to an intrinsically social dimension in the human neural activity, which may be essential for any subsequent consciousness of both one's own self and other selves.

However, this focus on self-referential thought may not capture all kinds of self-related thought. As noted earlier, there may be different facets of "selfness," and these facets may be related to

distinct brain areas. One approach to this multifaceted self (Fingelkurts et al. 2016) links the experience of selfhood to the activation of a default mode network (DMN). This network interconnects neural activity in frontal-left, posterior-right, and posterior-left areas of the cerebral cortex. Specific areas implicated are the left and right middle frontal gyri, bilateral frontal medial areas, left and right middle temporal and occipital gyri, and left and right precuneus. These are active and functionally synchronized during self-related tasks and when participants engage self-generated thoughts. The frontal-left structures are linked to the first-person perspective and the sense of agency (the witnessing observer). The posterior-right areas are linked to the experience of self as a localized embodied entity, emotion-related thoughts, and autobiographical memories (representational-emotional agency). The posterior-left areas are linked to the experience of thinking about oneself, including momentary narrative thoughts (reflective agency).

Research in anthropology and comparative biology indicates that the self is associated not with physical elements of the brain, but also with elements of the human genome. These lines of research culminate to the conclusion that the modern human mind is a mosaic of traits inherited from a common ancestry with close relatives (Sherwood et al. 2008). Indeed, the human brain is generally organized in a fashion similar to that of other primate species, and the greater the relation of those nonhuman species to humans, the more similar the organization. For example, the planum temporale, a surface feature of the cerebral cortex in the region of Wernicke's area, displays left hemisphere dominance in humans, bonobos, chimpanzees, gorillas, and orangutans.

However, human brains also have been enhanced via evolutionary specializations within particular domains. These include cognitive adaptations and linguistic adaptations that are correlated with enlargement of the neocortex and related structures. Several anatomical and molecular changes have occurred that seemingly reflect the modern human brain's high metabolic demand and enhanced synaptic plasticity. Illustrating this point, in humans higher-order unimodal and

multimodal cortical areas have grown disproportionately relative to primary cortical areas. Moreover, in comparisons of the brains of higher-order primate and the brains of humans, only humans have multiregion lateralized networks, which provide frontoparietal connectivity. Sherwood et al. (2008) maintain that this pattern of within-hemisphere connectivity distinguishes human brains from the brains of nonhuman primates.

Hominid DNA evidence leads to similar conclusions. Researchers have recently reproduced a complete genomic sequence of a Neanderthal woman (Prüfer et al. 2015). Only a small list of simple DNA sequence differences distinguished these Neanderthals from modern humans. A good deal of these differences implicated the biology of the neocortex, a finding that is consistent with the idea that evolution prompted the emergence of the modern human self.

A similar conclusion can be derived from studies that examine the brain structure alterations linked to various psychopathologies in which symptoms include alterations in the sense of self (Northoff 2014). Four of the most studied disorders involve self-distortions are schizophrenia, autism spectrum disorder, major depression, and borderline personality disorder. The relevant evidence indicates that distortions of the sense of self in these psychological disorders are associated with alterations in the brain's cortical midline system (including the perigenual anterior cingulate, inferior frontal gyrus, and insula), mirror neuron system (including the frontoparietal region [precentral gyrus, precuneus, supramarginal gyrus, inferior parietal lobule] and limbic system [anterior insula and anterior mesial frontal cortex]).

Additional findings link dysfunctions of the self to genetics. For example, Won et al. (2016) explored activity in regulatory regions of genes on the human genome that may be related to schizophrenia. These regions work like rheostats, increasing or decreasing a target gene's activities. Such rheostat-like loci regulate the activity of genes that are known to be crucial to brain development and that are very active early in brain development. It follows that disorders such as schizophrenia – and, by extension, the self-distortions that are

symptomatic of schizophrenia – may have a similar basis in the genetics that control brain development.

Researchers also have compared the genetics of nonhuman primate species to the human genome in order to gain insight into brain alterations that may have occurred during evolution. Relevant studies have examined corticogenesis (the process in which the cortex of the brain is created during neurodevelopment), and again have focused on those gene regions that regulate the expression of genes. Consistent with an evolutionary perspective, Reilly et al. (2015) concluded that many human lineage changes reflect alterations in gene regulation. That is, these alterations operate within older regulatory mechanisms and evolutionary processes essential for building the mammalian cortex, but they appear in modified form in humans. Saphire-Bernstein et al. (2011) forged a link among elements of the self, the brain, and genetics. They reported that varying genetic forms of the oxytocin receptor are associated with varying levels of self-esteem and depression.

There is a long way to go when trying to understand how evolution may have produced physical alterations in the brain and the human genome that link to the human experience of self. Nevertheless, the steady stream of results has taken substantial steps toward establishing the anatomical and genetic underpinnings of the self.

Conclusion

Psychologists have long had a fascination with the concept of “the self.” One thread of research into this topic has explored the possibility that any or all of the various facets of self-related thought have been promoted in humans by natural selection. Evidence favoring this idea comes from disparate sources. These include studies of archeology, cross-species studies of biology, psychology, and behavior, studies of anatomy and genetics, and studies of brain action and neural function. Individually, none of these sources is sufficient to establish unambiguously that the human self has emerged as a product of natural selection. However, the evidentiary converge provides strong support for this thesis.

Definition

Teaching is a procedure in which a donor conveys information to a receiver and aims to enrich his/her knowledge, a cooperative behavior in that one engages in an activity that benefits another, at some cost, or with no immediate benefit to itself.

Introduction

The values that describe human societies managed to create a culture that renders humans as the only species to be separated qualitatively from other animals. It is argued that the tendency of early humans to be curious in their nature fostered the learning of useful strategies that selectively became genetic capabilities and which rendered the ongoing development of culture as a remarkable achievement. Human species evolved over generations, and communication became more complex. Arbitrary cultural meanings are found to be assigned to animate and inanimate objects in the environment, allowing for a vivid indication that early culture initiations were occurring. As communication is a vital component in the realm of enculturation, language appeared to develop in parallel with human cultural values. Throughout a continuous, systematic progress, there is evidence of memory expansion and brain size increase that

facilitated and possibly co-interacted with the development of enculturation and the entry of humans in social norms. The ongoing evolution and the development of hierarchical structures within cultures rendered the role of educators vital for functional authority frameworks and the growth of civilized nations.

Teaching and Cumulative Culture

Knowledge is widely thought to underlie the success of humanity by allowing high-fidelity transmission of information and skills between individuals, facilitating both cumulative knowledge gain and normative culture. Teaching indicates signs of evolution, whose costs are eliminated by the inclusive benefits that result from the individual adapting and constantly seeking to acquire valuable information (Csibra and Gergely 2006). This leads to a narrow range of traits for which teaching would be efficacious and justifies the rarity of teaching in nature, its unusual distribution, and its highly specific nature. Further models that allow for cumulative cultural knowledge gain suggest that teaching evolved in humans because cumulative culture renders otherwise difficult-to-acquire valuable information available to teach. Interpretively, it resolves the mystery of why teaching should be widespread in human societies but extremely rare in other animals (Kirby et al. 2007). Compared to animal teaching, human teaching is a very general capability, reliant on high-fidelity mechanisms such as speech, instruction, and direct shaping, and it allows the transmission of complex information that could not be devised by a single individual (Hoppitt et al. 2008). Humans have undergone cumulative cultural evolution, which has in essence reduced reliance on information acquired asocially (Rapaport and Brown 2008) and allowed the transfer of knowledge and skills that would be difficult to learn without direct guidance and instruction. For instance, valuable information, concerning industrial practices or technological manufacture, has become available to teach through the accumulated efforts of many individuals. Potentially, teaching and cumulative culture

might have coevolved, extending the possibility to allow for cumulative knowledge gain by allowing individuals that have acquired the information to gather further knowledge that improves it (Taylor et al. 2007), simultaneously, making the information more fitness enhancing but more difficult to learn.

Key Characteristics of Teaching

Importance of Relatedness

From an evolutionary perspective, teachers do not gain any benefits unless the pupils learn, while the delayed benefits of teaching depend on both the teacher's efficacy and the pupil's aptitude. It is argued that high relatedness may favor the evolution of cooperation and, hence, teaching may be most common between closely related individuals (Hamilton 1964). Interpretively, teaching might be especially common as a form of parental care since the noticeable discrepancy in knowledge between adults and infants implies that parents can raise their offspring's potential fitness by assisting them to learn critical skills (Thornton 2007).

Behavioral Coordination

One of the most critical characteristics of teaching is the behavioral coordination of individuals because it serves to distinguish it from other forms of social learning and may allow for insight into its evolutionary history (Kirby et al. 2008). In standard social learning, naïve animals attend to knowledgeable individuals. Studies have shown that even the presence of an anesthetized conspecific is sufficient to cause naïve individuals to approach a food patch and acquire information (Laland and Plotkin 1991; Galef and Giraldeau 2001). On the other end of the spectrum, teaching is characterized by the interaction of a donor and a receiver of information that attend to each other and engage in different but coordinated behaviors. In other words, it is necessary for educators to modify their behaviors to foster learning in students; however, if students are unresponsive, learning will not occur. Efficient behavioral coordination is the product of the coevolution of

teacher and student strategies (Feldman and Zhivotovsky 1992). The coevolution would potentially result in mechanisms whereby each party responds to cues from the other. Behavioral coordination and feedback between individuals do have important implications for the debate over sensitivity and evaluation in teaching. It is vital that teachers respond sensitively to their audience's changing competence and underline noticeable signs of growth in students (Pearson 1989). This involves attributing knowledge to students and responding flexibly to changes in students' performance (Pearson 1989; Premack and Premack 1996). This can be achieved through showing sensitivity by adjusting the behavior in response to cues representing students' age and competence level. Teachers may demonstrate greater ability to track improvements in the abilities of individual students when there are fewer students to monitor and when the costs of a failure to learn are greater.

Adaptive Behaviors in Response to Learning

Teaching is designed by natural selection to fulfill the goal of promoting learning; an individual modifies their behavior accordingly to facilitate learning (Thornton and Raihani 2008). Some authors support that any human behavior involved in the transfer of declarative information is a form of communication in that senders influence the behavior of receivers. Functionally referential alarm calls are characterized for their immediate function, which rather disregards additional positive selection that would help individuals to learn. The immediate response instantly adopts alerting conspecifics to the presence of a particular type of predator so that it may provide appropriate reaction. Learning in this case is an incidental by-product, although infants may learn associations between given call types and predators simply by hearing calls in context (Seyfarth et al. 1980). Evolutionarily, it is shown that teaching may be the most parsimonious explanation for behavior. Widespread reports demonstrate that mothers in various species gradually allow their offspring opportunities to handle live prey (Caro and Hauser 1992; Kitchener 1999).

Studies on Learning in Other Species

Costly changes in maternal provisioning behavior in cheetahs and domestic cats were documented, as cubs grew older. Animals that were consistently exposed to live prey in the presence of their mother showed improved hunting skills compared to those who were merely exposed to prey alone (Rendell et al. 2010). Combined results are highly suggestive of teaching, and they support that selection would eliminate seemingly wasteful behavior such as giving young live prey that might escape unless it serves a function (Grafen 1984). The results derived out from studies of this nature suggest that adults give their young opportunities to handle live prey and facilitate their learning, fact that constitutes a parsimonious explanation for the striking changes in provisioning behavior (Cavalli-Sforza and Feldman 1981).

Procedural and Declarative Knowledge

Once procedural knowledge is gained, it tends to become implicit. Information that belongs in the realm of procedural knowledge lies outside of human awareness. It is argued that it can be also named as the "muscle memory" since the human body proceeds to operate physical tasks effortlessly after mastery is accomplished.

Categories of declarative knowledge are facts, world or personal history, and rules for mathematics operations. A key feature of declarative knowledge is that it is easy to express it in the form of words or symbols. Declarative procedures function explicitly and are expressed through the human consciousness. Individuals are consciously aware of their declarative understanding.

Controversy

The distinction between procedural and declarative knowledge is a controversial issue. This controversy of meaning-as-action versus meaning-as-context parallels the earlier psychological issue of behaviorism versus Gestaltism. However, the current debate reflects a more advanced understanding, being essentially mentalistic and having reference to internal states. The questions are refined intrinsic versus extrinsic computation,

intentional versus extensional contexts, the modularity/efficiency trade-off, and heuristic power versus logical consistency. What is most important is that the programmer possesses the ability to put knowledge anywhere in the system that can be used and that facts are conceptualized in the form of advice regarding their use. Research on procedural evolution is necessarily concerned with the nature of expertise. The representation of domain-dependent knowledge should be accessible by situational goals (Tehrani and Riede 2008); the problem of recognition; the trade-off with structural problem-solving techniques; and physical and mechanical analogies. Most important in studying children's programming is the role of learning. The emphasis is on learning how versus learning that and the importance of a carefully organized sequence of problems, solutions, and near misses to solutions. Compared to animal teaching, human teaching is a very general capability, reliant on high-fidelity mechanisms such as speech, instruction, and direct shaping, and it allows the transmission of complex information that could not be devised by a single individual (Hoppitt et al. 2008).

Conclusion

Teaching will evolve only where the costs to teachers facilitating learning in others are outweighed by the long-term fitness benefits they accrue once students have learned. Nevertheless, it needs to be taken into consideration that cases of individuals who tend to acquire information easily without assistance will render teaching as unlikely to be favored by selection. Hence, behavioral coordination should be facilitated from both the donor and the receiver in an attempt to maintain social structure, hierarchy, and cultivation of values within the frame of civilized communities. Signs of learning and teaching effectiveness in species other than humans indicate cohesive evolution of teaching, whereas the controversial debates concerning procedural and declarative knowledge allow for implications of knowledge complexity and constant evolution of human perspective, physically and mentally.

Definition

Evolutionary neuroscience is an interdisciplinary field of study which seeks to understand the evolution of the brain and nervous system and provides a

framework for interpreting evolutionary changes in the brain and brain component size or shape.

Introduction

The field of evolutionary neuroscience has provided us with an enormous amount of comparative data and relevant theoretical principles to support our current understanding of the evolution of the nervous system. Evolutionary neuroscientists are interested in understanding how the brain evolves and in reconstructing the natural history of the nervous system from a structural and functional perspective. Evidence of brain evolution can be documented through the lens of various biological fields, including biological anthropology, ethology, paleontology, comparative psychology, comparative neuroanatomy, cognitive science, and molecular biology and genetics. The brain, like other organs of the body, is a result of evolutionary processes which have shaped its structure and function. Some of these evolutionary forces have uniquely adapted each nervous system to the environment in which that species lives, while others (either due to shared environmental pressures or common developmental/phylogenetic/architectural plans) have generated remarkable similarities across species.

Comparative Studies

Often when studying the evolution of the nervous system, investigators will choose to perform a comparative study of extant (living) species that are united by a particular characteristic (i.e., feature or trait) and share a common evolutionary history. These characteristics are said to be homologous in nature, that is, they evolved only once and through a common ancestor, rather than through separate/independent evolution. Such studies are phylogenetic in nature and differ from other comparative studies in that the choice of species under investigation is guided by how closely related they are to one another (Butler and Hodos 2005). These studies help us learn more about the historical development of a lineage and are important as they help us identify evolutionary novelties in brain structure, when these novelties emerged within the lineage and how a particular

feature varies in closely related species. This allows the investigator to see if there are any common trends that unite the characteristics of the nervous system in the studied species (Butler and Hodos 2005) and may also help identify features which are unique to particular species (e.g., Krubitzer et al. 2011; Healy and Krebs 1996).

As an alternative to the phylogenetic approach, comparative studies may also focus their comparisons on species that show marked differences in a specific characteristic (e.g., behavioral differences such as sociality, aggression, or structural differences such as in the size of a particular brain structure) irrespective of their phylogenetic relatedness. These types of studies are primarily focused on examining the form and function of the nervous system in an adaptive context (e.g., Barton and Harvey 2000; Harvey and Krebs 1990) and providing insight into how environmental pressures uniquely shape the nervous system so it is adapted to challenges in a particular environment. Both adaptation and phylogenetic comparative studies are important as together they help paint a more complete picture of the evolutionary trajectory of the nervous system.

Brain Size

One of the most striking features when comparing brains across species is the notable difference in brain size. The brain, like all other parts of the body, undergoes a proportional increase/decrease with body size. Allometry is defined as changes in the size of an object (e.g., body or brain) which result in predictable changes in the size of its components (Striedter 2007). Using this mathematical approach allows evolutionary neuroscientists to undertake cross-species comparisons of the relative size of the brain (or its subcomponents) by removing the influence of body size and helping us identify which species have brains (or brain parts) that are smaller or larger (encephalized) than expected for their body size. In contrast, isometry implies that the size of the brain (or brain part) is as one would expect for an organism of its given body size (i.e., there has been no proportional change relative to body size).

When brain mass is plotted against body mass data for all mammalian species, it is apparent that brain size scales in an allometric fashion with body size. Most body parts are known to scale

allometrically with body size (Schmidt-Nielsen 1984), and comparative studies have demonstrated that relative brain size has shifted several times either up or down during the course of vertebrate evolution. While there is a certain amount of overlap in the data, these types of analyses have demonstrated that the major vertebrate groups (i.e., mammals, birds, reptiles, amphibians, and fish) differ quite markedly from one another in terms of relative brain size (Jerison 1973). When relative brain size is compared between these groups, mammals are shown to have the largest relative brain sizes of all vertebrate groups. The majority of mammals have relative brain sizes larger than birds, while birds in turn have larger relative brain sizes than reptiles and amphibians. Similarly, the cartilaginous fish (i.e., sharks, skates, and rays) are shown to have larger relative brain sizes than all other fish. Using this approach, comparative studies have identified that the human brain is markedly larger than one would expect for a mammal of its given body size (i.e., humans have relative brain sizes which far exceed that of all animals) (Manger et al. 2012, 2013). When we look at an overview of relative brain size within the various taxonomic groups, it becomes clear that relative brain size has increased independently in several different lineages (Northcutt 1981) dispelling the notion of a linear increase toward the human condition as supposed by early evolutionists. As pointed out by Striedter (2005), these increases in relative brain size within each lineage coincide with major radiations within the taxonomic groups; in other words, species diversity increased in groups soon after they underwent an increase in relative brain size (e.g., birds and mammals), and similarly species diversity decreased in groups that underwent a decrease in relative brain size (e.g., salamanders and newts). This suggests that there is a particular selective value associated with increases in relative brain size, with more encephalized species likely able to occupy new niches as well as better buffer themselves against environmental changes (Striedter 2005).

Brain Component Size

Brain size (both absolute and relative) is not the only element acting on species behavior, but may

be viewed as the sum of the individual components that make up the brain (i.e., brain parts, connections, and cellular and overlying neurochemical components) and collectively determine its function. An alternative application of the allometric approach has been to look for structural and functional correlations between the individual components of the brain. The resulting data has led to an interesting ongoing debate within the field of evolutionary neuroscience with two major camps emerging: those who argue that most changes in the brain are due to evolutionary constraints and those who argue that most changes in the brain occur as a result of mosaic evolution (adaptations). Under the influence of constraints, one would expect evidence that the underlying components of the brain change in a concerted manner (i.e., individual brain parts scale up or down in a proportional way), whereas in mosaic evolution, one would expect that individual brain parts would be free to vary in size as selective pressures favor particular functions/behaviors over others. Evidence for both concerted (Finlay and Darlington 1995) and mosaic (Barton and Harvey 2000) evolutionary changes in brain component size have been presented. Overall, the majority of changes in brain component size appear to follow a concerted evolutionary process which generally hold true across most mammals, but mosaic evolution has also played a significant role, albeit occurring more infrequently.

Functional Significance of Changes in the Brain or Brain Component Size

While studies on the functional consequence of changes in relative brain size are numerous, it is important to note that conclusions derived from these studies are dependent on the techniques used for comparison as well as the species and level of organization under study, so extrapolating these findings to other groups should be done with caution. That being said, there are several lines of evidence for behavioral correlates with relative brain size. For example, correlations have been uncovered between altricial behavior (i.e., hatchlings born in an underdeveloped state) and encephalization in birds. Hatchlings that are underdeveloped tend to have larger relative brain sizes

than their less feeble counterparts (Iwanuk and Nelson 2003). Others have argued for correlations between relative brain size and life span in primates (Allman et al. 1993), relative brain size and diet in bats (Hutcheon et al. 2002) and in primates (Clutton-Brock and Harvey 1980), as well as relative brain size and foraging strategy in birds (Bennet and Harvey 1985; Clayton et al. 2001) to mention a few. Several studies have also argued in favor of correlations between relative brain size and aspects of sociality (e.g., Dunbar 1998). All these observations and accompanying hypotheses point to the fact that explaining the biological significance of changes in relative brain size is a rather complicated task often filled with controversies and that it is rather simplistic to expect that a measure as broad as brain size should be the result of a single selective pressure or likewise constrained by a single mechanism (Striedter 2005).

Evidence for the functional significance of changes in brain component size have largely come from physiological studies and have added support to the idea that brain evolution proceeds in a mosaic fashion. These physiological mapping studies have demonstrated that species with highly developed sensory or motor abilities also tend to have larger corresponding motor and sensory areas within the neocortex. A classic example is the enlarged representation of the paw/forelimb in the raccoon motor and somatosensory cortex, a feature which matches the behavioral observations of remarkable dexterity demonstrated by the raccoon paw, in comparison to other carnivores (Welker and Campos 1963). Similarly, otter species that use their forepaws more extensively also have larger representations of the forepaw in their somatosensory cortex (Radinsky 1968), and sensitive appendages like the pig's snout (Finger 2000) or the platypus bill (Pettigrew et al. 1998) used for exploring the environment also have relatively enlarged representations in the sensory cortex.

However, comparative studies have not only indicated that brain components can increase (or decrease) in size, but there also appears to be evidence that new components may be added, thus theoretically increasingly the complexity of the system. For example, it is well known that the

cerebral cortex (i.e., the outer surface of the brain) may be partitioned into different cortical regions each with their own unique cellular anatomy and functional correlates. This outline of the cortical surface into a brain map was initially described through the pioneering work of Korbinian Brodmann who went on to describe some 52 cortical brain regions. Brodmann's map has been modified over the years with the addition of physiological and connectional studies, but his approach of mapping the cortical surface has been used successfully in mapping the brains of various species and providing comparative data to evaluate potential evolutionary changes in cortical regions. These studies have confirmed what Brodmann observed which is that the number of cortical areas differs between species. For example, the visual system of the macaque monkey has been shown to consist of around 30 distinct cortical areas (van Essen et al. 1992), while comparative studies on smaller brained mammals (e.g., mole or hedgehog) indicate that these species have far fewer cortical areas (Catania et al. 1999; Northcutt and Kaas 1995). These studies suggest that the number of cortical areas has increased with the evolution of large brains. Collectively, comparative studies at the level of the cortical area, as well as similar studies on smaller subunits of the nervous system (e.g., Bianchi et al. 2011; Spocter et al. 2015), emphasize that changes in size are not the sole factor to consider when looking at the evolution of the brain.

Conclusion

The field of evolutionary neuroscience has contributed significantly toward our understanding of the processes that have shaped the nervous system and that permit variation in the form and function of the brain. From a historical perspective, the field of evolutionary neuroscience is still emerging in many ways, coopting many of its ideas from that of general evolutionary biology (Striedter 2007). The relevance of evolutionary neuroscience in unraveling the mysteries of the human brain as well as the mechanisms that unite the function of all nervous systems remains a crucial contribution.

Definition

The emergence of stone tools represents a significant milestone in hominin evolution culminating in the uniquely flexible abilities of humans to use and make tools. Studies on the evolution of tool use are aimed at reconstructing the evolutionary history of this adaptation. Although this area of inquiry has historically been the interest of archeologists, the integration of modern brain imaging techniques and the accumulation of comparative behavioral data in other animals have continued to widen its scope of study.

Introduction

The archeological record has revealed that humans and human ancestors have had a long reliance on stone tools (Larsen 2008). Since the early Pliocene (approximately three million years ago), the frequency and complexity of stone tools, as uncovered from archeological sites, gradually increased with a major expansion in tool technology occurring within the last 12,000 years (Boyd and Silk 2009), suggesting that tool use likely

conferred our ancestors with an adaptive advantage. This long co-occurrence/coevolution of tool usage and humans created a “biocultural feedback system” (Washburn 1960), whereby our evolved abilities not only allowed us to shape these tools but our interactions with them (and the act of shaping tools), resulting in changes to our underlying biology (e.g., changes in the hand and brain). Given the immense reliance and flexibility of humans at shaping and using tools, one would be forgiven for thinking that tool usage is a uniquely human feature. However, evidence garnered from the hominin fossil record (Asfaw et al. 1999; Semaw et al. 1997; Semaw 2006) and observations of tool usage in extant species (e.g., Rutz et al. 2016; Krützen et al. 2005; Whiten et al. 1999) challenge this assertion.

Comparative Tool Use in Other Species

One of the challenges with comparative behavioral research is being mindful of the pitfalls of anthropomorphism or indirectly setting up a *scala naturae* in our interpretations (Hodos and Campbell 1969). Therefore, it is important to clearly define the phenomena under investigation and to outline the associated criteria that make this comparable between species. When it comes to comparing data on tool use in different species, it is foremost important to define what a “tool” is and what are the criteria for usage. In this regard, a tool is usually defined as an object (which is not part of or produced by the animal’s body) that is used to attain a particular goal (Shumaker et al. 2011). Examples of this include the use of objects such as twigs to gather a food source as observed in birds (Rutz et al. 2016). Perhaps the most elegant of these observations are those seen in the New Caledonian crow appearing to even safeguard their preferred tools between tasks (e.g., Hunt and Uomini 2016; Uomini and Hunt 2017). A wide range of animals are known to use tools with a recent compendium indicating the observation of nonhuman tool use in nine classes of animals (sea urchins, insects, spiders, crabs, snails, octopi, fish, birds, and mammals) spanning four phyla (Shumaker et al. 2011). When examined across this wide range of species, the pattern of tool use behavior aligns poorly with our

understanding of brain size and neurological complexity (Shumaker et al. 2011; Sanz et al. 2013; Lemert and Spocter 2018a, b), suggesting that a further criterion separates the tool use behavior of humans from that of other species. Shumaker et al. (2011) assert that the real challenge is not only in the making of tools but in flexibly altering the sequence of actions during toolmaking especially when faced with novel challenges. As highlighted by Gunturken (2014), only some primate (Fragaszy et al. 2013), parrot and corvid species (Auersperg et al. 2011) have met this criterion, suggesting a much narrower band of animals for comparison. Toth and Schick (2013) suggest tool use in non-primates is driven by instinct whereas primates (including humans and other great apes) exhibit a gradual acquisition of tool use abilities (e.g., Shumaker et al. 2011) likely mediated through social learning and mimicry. Among the nonhuman primates, these abilities are most accentuated in that of our closest living relatives, the chimpanzees. Like humans, tool use behavior in chimpanzees is learned through the observation of other conspecifics and through trial and error (McGrew 1992, 2004). These behaviors include a number of complex behaviors including observations of chimpanzees deliberately shaping twigs for use in termite fishing (Whiten et al. 1999), evidence of geographic differences in tool culture between groups (Toth and Schick 2009; Whiten et al. 2009), and the ability of bonobo chimpanzees in learning to craft simple (Oldowan like) stone tools remarkably similar to that found in the hominin fossil record (Schick et al. 1999; Toth et al. 2006). Collectively, these observations suggest that humans share some components of our neural framework important for tool use with chimpanzees and that this framework likely helped support the emergence and subsequent evolution of tool use in fossil hominins.

The Hominin Fossil Record and Tool Use

Based on the fossil record, fossil hominins emerged on the continent of Africa some 7–8 million years ago and diversified into a numerous hominin forms (Larsen 2008). One can group these hominins into three main groups: (1) the

pre-australopithecines, which included more ape-like hominins dated between 7 and 4 million years ago; (2) the australopithecines dated between 3 and 2.5 million years; and (3) fossils belonging to the group *Homo*, dated from around 2–2.8 million years ago (Larsen 2008). In addition to these three major groups, there also evolved a group of later australopithecines (*Paranthropus robustus*, *Paranthropus boisei*) which, although sympatric with *Homo* (up until one million years ago), is believed to be an evolutionary dead end due to their rather specialized cranio-dental morphology (Grine 1988).

The Australopithecines

The early australopithecines are believed to be ancestral to *Homo* (Johanson 2004; Tattersall 2008) from which our species *Homo sapiens* emerged at around 160,000 years before the present (Larsen 2008). These early australopithecines were small-brained hominins, well adapted to bipedalism. Comparative endocast morphology suggests that early australopithecines (belonging to the species *Australopithecus africanus* and *Australopithecus afarensis*) had undergone slight brain expansion and restructuring in the neocortex, with a relative increase in the posterior parietal association cortex, along with a concomitant reduction in the size of primary visual cortex (Holloway 1981; Holloway and Kimbel 1986). Interestingly, the posterior parietal cortex coincides with the location of the temporoparietal area (Tpt), a key language area in humans, which is smaller in size in chimpanzees (Spocter et al. 2010). Among these early australopithecines, a hominin known as *Australopithecus garhi* (Asfaw et al. 1999) is considered one of the earliest candidate toolmakers. Remains from this species were found in the same region and in fossiliferous deposits of similar age (between 2.6 and 2.5 mya) to stone tools recovered from Ethiopia (Semaw et al. 1997; Semaw 2000, 2006). Stone tools from these sites mark the beginning of what is called the Paleolithic.

Early *Homo*

With the emergence of *Homo* (at around two million years), we see evidence for marked

hominin brain expansion (Klein 2009). The earliest stone tools are referred to as “Oldowan” stone tools and are named after the site Olduvai Gorge (Hovers and Braun 2009). By approximately 2.3 million years ago, Oldowan sites became numerous and widespread on the African continent and are attributed to the toolmaking abilities of *Homo habilis* and *Homo rudolfensis* (Schick and Toth 2006; Toth and Schick 2010). Oldowan tools are simple tools made by deliberately hitting one rock against one another and striking off stone flakes (Toth 1985). The emergence of these tools was a significant step in hominin evolution, and it is perhaps no coincidence that there is an alignment between the appearance of stone tools in the fossil record and the marked expansion in brain size in *Homo* (Holloway et al. 2004; Toth and Schick 2010). Some of the most striking evidence emerging from the study of Oldowan tools is the observations that hominins were clearly sourcing these materials from different localities and taking them to different sites (Leakey 1971; Schick and Toth 1993, 2006).

By around 1.8 million years ago, the larger brained *Homo ergaster*/*Homo erectus* appears in Africa and Asia (Lordkipanidze et al. 2013; Manger et al. 2012). It was during this time that some of the most striking evidence of stone tool evolution occurred. In particular, we see the development of new stone tools, called Acheulean, which were markedly different from the simple Oldowan form (Klein 2009, 2013; Lepre et al. 2011). This new stone tool industry was characterized by the shaping of handaxes, cleavers, and picks but still used the flaking approach of the Oldowan. Toth and Schick (2009) have demonstrated experimentally that the manufacture of Acheulean tools require a larger number of cognitive decisions and procedures than those required for making Oldowan tools and that these tools could be used efficiently in animal butchery (Schick and Toth 1993; Toth and Schick 2009). This tool industry became more sophisticated with time, and there is a suggestion that this refinement in the technology might even indicate an appreciation of aesthetics (Schick and Toth 1993).

Later *Homo*

Given the observation that stone tool sites continued to proliferate along with the rapid expansion of the genus *Homo*, it is parsimonious to assume that species from this genus are responsible for the majority of early stone tools uncovered. In both Africa and Europe, later *Homo* belonging to the taxonomic group “archaic *Homo sapiens*” include the species *Homo heidelbergensis* and *Homo neanderthalensis* (Klein 2009). It is during this time that a transition in stone tool industries occurs from later Acheulean to the Middle Paleolithic. Stone tools from the Middle Paleolithic are characterized by flaked tools (e.g., scrapers and points) which were often made by carefully shaping the external surface through striking off flakes, likely requiring higher cognitive skills. In addition, during this time period, there is increasing evidence of fire use at habitation sites (Mellars 1996; Roebroeks and Villa 2011) which would have conferred additional advantages to hominins from this time period.

Modern Humans

By around 160,000 years ago, fossils found in parts of Africa and the Near East are considered to belong to early *H. sapiens* and are associated with Middle Paleolithic which then progressed to Upper Paleolithic as humans became more widespread (Klein 2009). During the Upper Paleolithic, modern hunter–gatherers had tools consisting of long, thin blade technologies which served as efficient cutting tools (Pettitt 2013). Tools during this period continued to be refined becoming increasingly smaller and forming part of composite tools (e.g., used as points or knives) (Klein 2009). The appearance of composite tools was a major achievement in tool use, requiring arguably a higher level of planning and forethought than previous tools (Ambrose 2010). Composite tools were made of two or more materials that were prepared separately before being combined into a single tool (Ambrose 2010). During this time period we also see the use of other materials such as bone and ivory in the making of tools (Klein 2009; Pettitt 2013) as well as the development of mats and textiles (Adovasio

et al. 1996), symbolic expression through the development of ornamentation and figurines (White 2003; Cook 2013), and the evidence of engraving and painting (Clottes and Arnaud 2003; White 2003; Cook 2013).

Tool Use and Reorganization of the Brain

As shown through observations from the fossil record, the gradual increase in tool complexity and associated expansion in hominin brain size suggest that tool usage must have been adaptive and resulted in some degree of brain reorganization (Teschke et al. 2013). While this is still an emerging area of research, comparative neuroimaging data has provided some interesting evidence to support this claim. In particular, evidence for reorganization in the brain following tool use has been shown in both monkeys and humans (Iriki et al. 2001; Maravita et al. 2002). Exposure to a tool using task resulted in an adjustment in body perception, with both species perceiving the tools as extensions of their individual bodies (Iriki et al. 2001; Maravita et al. 2002). Similarly, there are species-specific differences in the somatotopic representation of the hand and foot in humans and monkeys (Hashimoto et al. 2013). In particular, while both humans and monkeys have separate somatotopic units for the fingers, the human foot representation has undergone reorganization away from the fused map of all five toes (as found in monkeys) toward a dedicated somatotopic unit for the big toe markedly separate from the other toes (Hashimoto et al. 2013). This unique organizational feature is hypothesized to be indicative of the shift toward bipedalism. Furthermore, there is also evidence to suggest that tool use in non-primates might also be associated with reorganization in the brain. In particular, a recent study of the tool-making New Caledonian crows has indicated that this species has evolved enlarged brain areas involved in associative and motor learning, suggesting an independent evolution of cognitive skills supporting tool making in both corvids and primates (Mehlhorn et al. 2010). One more area that has made significant contributions to the question of tool use and which promises much in expanding our understanding of the evolution of tool use has been the comparative study of hand

morphology in primates (Stout 2002; Marzke et al. 1998; Marzke's 2013).

Conclusion

The evolution of stone tools was a significant step in hominin evolution, undoubtedly serving as an important input for the development of other biocultural features. Ongoing inquiry in this field has helped to advance our understanding of own tool abilities to use tools and the evolutionary history of our species. This area of inquiry has also helped gain much needed insight into species differences in tool use and how human tool use differs from that of other species.

Evolution of Virulence

Nicholas Primavera

SUNY New Paltz, New Paltz, NY, USA

[Differences in viral infection](#)

Introduction

Within nature, there exist a variety of parasites that can cause a wide range of problems to the infected host. Some parasites are relatively benign, while others can cause serious medical complications. The simplified answer is that certain levels of virulence were naturally selected to be beneficial to the parasite over others.

Virulence and Trade-offs

The term virulence can have several different definitions depending on the context of the

discussion. According to Cressler et al., “The most general definition of virulence is the reduction in host fitness caused by infection. In mathematical models, virulence is quantified as an infection-induced increase in host mortality rate or reduction in host reproductive rate. In experimental or observational data, virulence is often quantified by measures of ‘harm’ done by the parasite, such as host anemia, weight loss, or morbidity, assuming that this harm is correlated with negative impacts on host fitness” (Cressler et al. 2015). For the purpose of this excerpt, virulence will refer to the mortality rate that is caused by the infection. According to the Centers for Disease Control (CDC), some of the most notably virulent diseases include those with very high rates of infection, such as Ebola, HIV/AIDS, tuberculosis, and pneumonia.

When it comes to understanding the evolution of virulence, there are several important factors to take into consideration. Firstly, the variation of virulence between different parasites can best be explained by what is known as “evolutionary trade-offs.” Trade-offs are best defined as “A situation that occurs when a change in one trait increases fitness, but a simultaneous change in another trait reduces fitness, thus preventing the organism from optimizing both changes” (Oxford References 2010). For example, there are two different levels that influenced differences regarding virulence. The first level is the population of the host. The greater the number of potential hosts, the greater the opportunity the parasite has to infect them. However, the parasite is only as successful as its ability to survive within the host without being immediately destroyed by the immune system, antibiotics, or other measures. Hence, the success regarding the host population is also inherently related to the success regarding the interactions within a host (Van Baalen and Sabelis 1995).

The second level that influenced differences within virulence is within the host’s population. For example, this means that the success of the parasite is also dependent on factors such as on-going infections, different parasites already present, and many other factors. Cressler states that “These interactions may be antagonistic,

when parasites compete for resources or provoke a cross-reactive immune response, or they may be facilitative, when closely related strains cooperate or cotransmit” (Cressler et al. 2015). It is important to note that the parasite must be successful regarding both of these levels; therefore, this model can help explain differences regarding virulence. Mideo et al. report that “Because parasites must ultimately be successful at both the within-and between-host scales, virulence is expected to evolve to balance these potentially conflicting selection pressures” (Mideo et al. 2008).

Conclusion

The information provided within this expert is a cursory exploration into the evolution of virulence. There are numerous different theoretical and empirical literature that make the case for different approaches to this topic. It is important to note that the biological processes that take place cannot be overlooked, as they play a key role in understanding the fundamentals regarding the evolution of virulence.

Evolution's Empress: Darwinian Perspectives on the Nature of Women

Maryanne L. Fisher
Department of Psychology, Saint Mary's
University, Halifax, NS, Canada

Definition

An edited book that focusses on women as active agents within the evolutionary process.

Introduction

Evolution's Empress: Darwinian Perspectives on the Nature of Women was published by Oxford University Press in 2013 and co-edited by Maryanne Fisher, Justin Garcia, and Rosemarie Sokol-Chang. It contains 22 chapters, plus an additional foreword by Sarah Blaffer Hrdy, and an Introduction. The chapters span a range of topics such as health and reproduction, competition and cooperation, parenting, and mating and communication. The goal of the editors was to integrate evolutionary and feminist perspectives, showing that they can work together to provide novel insights into behavior.

Integrating Evolutionary and Feminist Perspectives

In the Introduction, the editors of *Evolution's Empress* propose that there can be a meaningful reconciliation between the feminist scholarship and that based on an evolutionary framework. They acknowledge that both of these broad areas are

grounded in different histories and consequently often arrive at disparate conclusions. Those studying behavior using an evolutionary perspective rely on the scientific method, espousing objectivity, and believe they are building programs of research based on past, objective research. Feminist scholars often rely on qualitative methods, question the existence of objectivity, and propose that research does carry real-world social and political consequences. The editors review a growing dissatisfaction within the field of evolutionary psychology with respect to how women have been viewed as passive, or the neglect of topics that are critical for women, such as mothering, female alliances, and female physiology. Thus, one aim of the editors was to show that women have a leading rather than backseat role in human evolution.

Sex Roles, Aggression, Competition, and Cooperation

Evolution's Empress is divided into five sections. Section one, "Sex Roles, Aggression, Competition, and Cooperation," starts with an examination of female social relationships and contains four chapters. The section begins with Maryanne Fisher's overview of the topic of women's intrasexual competition for mates. It moves onto a chapter by Laurette Liesen, who analyses female aggression, alliance development, and how women view status. Liza Moscovice examines female alliances within the bonobo, a great ape that is closely aligned genetically with humans. This section ends with a chapter by Patricia Gowaty who presents the development of theoretical (and mathematical) predictions pertaining to sex differentiated behavior and the study of individual differences.

Mothering and Parenting

Section two contains five chapters. It begins with Kathryn Coe and Craig Palmer discussing the role of women in transmitting traditions regarding cooking and storytelling. Nicole Cameron and Justin Garcia then review the extraordinary and

distinct biological contributions that maternal effects have on adaptive offspring development. In their chapter on flexible parenting strategies, Lesley Newson and Peter Richerson investigate diverse parenting behavior and show that one commonality is female cooperation in the raising of children. Rosemarie Sokol-Chang suggests that listeners are responsive to vocalizations from attachment partners, proposing that these vocalizations have led women to solicit help in child rearing. Laura Betzig authors the last chapter in this section and reviews historical evidence on conflict between fathers and sons, showing that sons win conflicts when they have strong mothers.

Health and Reproduction

Section three contains four chapters. To start, Chris Reiber demonstrates how limited knowledge exists for women's reproductive physiology and the important contributing role that an evolutionary feminist perspective may play in furthering this area. In her chapter, Bobbi Low uses a life history/behavioral ecology approach to explore human fertility, as it relates to social, cultural, and ecological factors. One theme in Low's chapter, the trade-off between present and future reproduction, is the focus of the chapter by Johannes Johow, Eckart Voland, and Kai Willführ. They examine grandmothers, in particular, and contend that grandmothering is based on relevant conditions, including whether they are a grandmother based on their son's or daughter's reproduction. This theme of present or future considerations carries into the last chapter in this section by Michelle Escasa-Dorne, Sharon Young, and Peter Gray who explore woman's life history decisions in terms of childcare and views of romantic relationships, as influenced by life course development.

Mating and Communication

In the first of four chapters in this section, Linda Fedigan and Katharine Jack discuss, as an example species, female white-faced capuchins' active

rather than passive role in male mating strategies and throughout the full reproductive process. David Frederick, Tania Reynolds, and Maryanne Fisher present how women's choice of mates across diverse circumstances reflects flexibility in mating strategy. One trait, humor, is the focus of a chapter by Christopher Wilbur and Lorne Campbell. They discuss how women's choice of men with humor has actively shaped men's evolutionary history. In the last chapter in this section, Elisabeth Oberzaucher reviews sex differences in communication styles as a possible explanation for global inequality.

New Disciplinary Frontiers

The last section contains five chapters, spanning a considerable range of topics that collectively demonstrate how evolutionary and feminist perspectives may be integrated, leading to novel research developments. Tami Meredith presents how previously documented sex differences are better understood when one includes examination of motivations. She concludes that many of the sex differences are not absolute, but instead rely on different motivations, or occur at different frequencies. Nancy Easterlin continues with this theme, suggesting that sex differences do not necessarily imply differences in value. She uses the example of Brontë's novel *Jane Eyre* to show that evolved differences do not determine social outcomes but instead allow one to explore male control of female's strategies related to reproductive fitness and personal autonomy within pair-bonds. Julie Seaman reviews the necessity for a merger between feminist legal scholars and evolutionary psychologists, which would lead to insights of the latter group to be incorporated and thereby enable a deeper understanding of the human behavior that the law seeks to shape and regulate. Michele Pridmore-Brown combines queer theory with research on cooperative breeding to explore the "queering" of nature and the biologization of culture. Leslie Heywood, in the final chapter of the book, applies the extended synthesis of evolutionary biology as a way to resolve conflict and facilitate a conversation between evolutionary

psychology and feminist theory. She clarifies with several precise examples how the extended synthesis may serve to mediate the central tenets of feminist theory and those within evolutionary psychology.

Conclusion

The aim of the editors of *Evolution's Empress: Darwinian Perspectives on the Nature of Women* was to collect chapters that represent the range of research on women's active role in evolution. These chapters show, to varying extents, the ways in which evolutionary perspectives of human behavior and the feminist scholarship may be integrated, yielding novel directions for research. They contend that prior research that overlooks the inclusion of women and their viewpoints leads to the default and often erroneous conclusion that women are like men. They further posit that research on sex differences is of high importance but must consider women in a way that reflects their active role in human evolution. This book represents the contemporary shift from seeing women as passive to active agents within disciplines that rely on an evolutionary framework.

Evolutionary Arms Race

Gordon G. Gallup¹ and Rebecca L. Burch²

¹State University of New York at Albany, Albany, NY, USA

²State University of New York at Oswego, Oswego, NY, USA

Synonyms

Coevolution of the sexes; Intrasexual selection

Definition

The positive feedback loop created as genes, traits, sexes, or species complete and develop adaptations and counteradaptations to each other in order to optimize their fitness. In this case, it is in reference to the human sexes.

Introduction

A recurring feature of street slang is the phrase “size matters.” Growing evidence suggests that when it comes to human reproductive competition and genital morphology, size does matter.

The Evolutionary Arms Race and Genitalia

Gallup et al. (2003) devised a way to simulate sexual encounters under laboratory conditions to test what has come to be known as the semen displacement hypothesis. According to this hypothesis, sperm competition among human

males not only has led to larger ejaculates that contained more sperm but the human penis may also have evolved as mechanical means of competing with rival male semen in the female reproductive tract. The unique configuration of the human penis with its enlarged, bulbous glans at the head of the penis accompanied by the coronal ridge, which encircles the glans at the interface between the glans and the shaft of the penis, evolved to cope and compete with the presence of semen left by other males in the female’s reproductive tract by scooping and displacing the left-over semen from her prior suitors back away from the cervix to enable the male to substitute his semen for those of his rivals.

To test this hypothesis, Gallup et al. (2003) simulated sexual encounters under laboratory conditions using an array of artificial human genitals. The human penises consisted of latex dildos of different shapes and sizes, and the vaginas consisted of commercially available latex devices engineered to fit over the penis in such a way that males could use the latex vagina to masturbate. Gallup et al. (2003) also concocted different recipes for producing simulated semen which could be introduced into the artificial vaginas. Semen displacement trials involved inserting different artificial penises into the vaginas that had been loaded with simulated semen so that they could measure/quantify resulting variation in the magnitude of semen displacement.

Gallup et al. (2003) discovered that artificial penises that approximated human penis morphology displaced significantly more semen than did those of other shapes. They also discovered that the magnitude of semen displacement was directly proportional to the depth of insertion of the penis into the vagina. Follow-up questionnaire data included in the same paper showed that both men and women in committed relationships reported that following periods of either separation or allegations of female infidelity (as proxies for insemination by rival males), males engaged in significantly deeper and more vigorous penile thrusting during intercourse which would function to affect more complete displacement of rival male semen from the female’s vagina.

Conclusion

These findings bear directly on the possibility of a genital evolutionary arms race during human evolutionary history. With the emergence of semen displacement as another sperm competition strategy there may have been selective pressure operating on males to deposit semen in the deepest and most remote parts of the female vagina to minimize semen displacement by other males. This in turn could have put a premium on the development of bigger and longer penises that could more effectively access and displace semen left by other males from the most remote areas of the vagina. That in turn could have led to an evolutionary arms race which gave rise to the fact that among the other great apes which are our closest living relatives, the human penis is the largest, longest, and most peculiarly configured with an enlarged glans and coronal ridge.

To return to the question does size matter, the evidence suggests that as a consequence of sperm competition and the emergence of semen displacement during human evolutionary history, size did and may continue to matter when it comes to intrasexual competition for paternity among human males.

Definition

There has been an ongoing uneasy relationship between evolutionary biology and feminism(s) due to highly differing perspectives about objectivity in science, issues of sex differences, and the role of biology versus social and cultural construction.

Introduction

The tension between evolutionary biology and feminism(s) is palpable when it comes to understanding and explaining human behavior. At times, there seems to be no space for integrating the two perspectives: for example, Birke (2017) discusses how biological sex (i.e., anatomically female or male) and more generally the “ghost of biology” still remains problematic for feminist thought. Typically, feminists often view evolutionary based research as anti-feminist, reductionist, and neglecting the inclusion of social and cultural influences. This tension has been

documented for at least four decades by a range of scholars (Fausto-Sterling 1997; Fedigan 1986; Fisher et al. *in press*, 2013; Gowaty 1997; Hager 1997; Heywood 2013; Hrdy 1981; Kelly 2014; Nier and Campbell 2013).

One important consideration is that there is no unitary, integrated theory that can be accurately called feminism, as there exist many different variants and perspectives. Thus, there is no central, general theory that holds feminist views together (Eagly and Wood 2011); even the terms “feminist” and “theory” are debated within the feminist community (see Radtke 2017, for a review). The very heart of third-wave feminism is the reliance on multiple perspectives/multivocality and an intersectional approach leading to inclusivity and nonjudgment, rather than synthesis with theoretical justification that leads to “differences” (Snyder 2008). This issue aside, gender construction, sex, and human-focused research are considered to be comfort zones for exploring feminist issues (Åsberg and Birke 2010).

Those using an evolutionary perspective tend to ground their work in the scientific method and evolutionary theory. They form inquiries using past research that they perceive as inherently objective (i.e., value free), rather than subjective. In contrast, those working in feminist areas question this very objectivity (see Hankinson Nelson 2017) and have indicated the numerous ways bias enters the scientific method, as well as the fact that research has real-world social and political effects (Fisher et al. 2013). One example is simply the language used in biology and medical texts to explain human fertilization: the ovum is described as passive while the sperm is described as active (for this and other examples, see Hankinson Nelson 2017). Fisher et al. (*in press*) document that the key arguments used by feminists pertain to the analysis of evolutionary scholars when biological, social, cultural influences collide to shape human sexuality and how the latter generalize their findings.

One particular source of disagreement rests on evolutionary scholars’ reliance on parental investment theory. Parental investment theory (Trivers 1972) leads to conclusions of sexual inequalities,

such as women’s obligatory investment in pregnancy and children, women’s proportionately lower reproductive variance than men’s reproductive variance, and women’s higher choosiness in mate selection as compared to men. Such conclusions are not necessarily accurate or as applicable to primates as they are to other animals (see Gowaty 2013; Heywood 2013; Hrdy 1986). Feminists argue that this approach to human sexuality reinforces sexual double standards, while simultaneously neglecting any action or thinking that would reduce or remove social inequalities and injustices, especially directed at women and minority populations. Further, feminist scholars often see research on sex differences enforcing heteronormativity/heterosexuality, propagating and supporting stereotypical and ethnocentric beauty standards for women, and rationalizing or normalizing harmful behaviors of men towards women (e.g., speculation about the adaptive function of rape [Thornhill and Palmer 2001], family conflict [Daly and Wilson 1999], or domestic violence [Wilson and Daly 1998]).

The role of social constructionism in feminist scholarship also prohibits a strong integration with evolutionary viewpoints and is the cornerstone of much feminist writing (e.g., Heywood 2013). Social constructionism generally refers to “the belief that rather than our living in a readily knowable ‘out there’ reality, we dwell in a world that is socially constructed, constructed by our experiences with others, and validated consensually and communally” (Barkow 2006, p. 24). According to typical feminist scholars, evolutionary theorizing rests on a foundation of biological essentialism and biological determinism and rejects social and cultural factors (e.g., Eagly and Wood 2011). This divide may be artificial, given as Barkow (2006) reviews: we are a culture-bearing species, meaning we rely on socially transmitted information for our survival and reproduction. Any argument in favor of social construction demands that humans are able to socially transmit and receive information, and evolutionary perspectives show that this capacity has itself evolved. The human brain has changed over time to adapt to increasingly complex social environments, and we need to be able

to acquire and then use information about our local environmental (i.e., geographic, social, familial, cultural) conditions. This information leads to successful responses within these environments, which means that humans possess evolved mechanisms that permit – and even rely on – social construction. Social construction is not *against* biological explanations of behavior but instead is synergistic; both are constrained by our evolved brains and bodies. Indeed, our only option is to agree with the assertion by Janicki and Krebs (1998, p. 202): “purely biological models will not be able to supply a full account of human behavior without reference to cultural process.”

There have been numerous attempts to integrate evolutionary perspectives with feminist scholarship. These attempts generally are aimed at arriving to a more holistic comprehension of humans, particularly in terms of sex and gender. Relatively recent developments in evolutionary theory, from the modern synthesis to the extended synthesis of evolutionary biology, show noteworthy potential for integrating feminist and evolutionary approaches to the study of gender, sex, and sexuality in behavioral sciences (see Garcia and Heywood 2016). These types of developments showcase social environments are as significant a consideration as material biology and highlight how they are co-constitutive such that one responds to the other, typically in heritable ways. Similar frameworks in behavioral ecology, cultural evolution, and gene-culture co-evolution have been created and view biological species in a social environmental context. We note that, like Campbell (2006), acknowledging the importance of culture in shaping human factors such as gender/sex is not asserting that there is an absence of biological influences to consider.

There have been decades worth of biologists who are feminists (e.g., Haraway 1978), as well as those working within feminist evolutionary biology (e.g., Fausto-Sterling et al. 1997; Smuts 1995). There is notable interest in the area, as seen by the formation of the Feminist Evolutionary Perspectives Society in 2009 (Sokol-Chang and Fisher 2013). There are now special issues of peer-reviewed journals have been devoted to the topic, as well as entire books and edited

volumes, including several feminist rebuttals (see Fisher et al. [in press](#), for a review).

Conclusion

In summary, evolutionary theory has existed for well over a century, and feminist responses to it emerged shortly after. Additionally, feminisms have long studied the effect of culture, which in turn is created by evolved minds. However, both disciplines have historically failed to see where integration was obvious, necessary, or beneficial. While strides have been made, we argue that there remains much work to be done. This work needs to come from both fields. We previously noted that incorporating feminist views within evolutionary perspectives has made inroads, but there is resistance for the reverse transaction. These impediments must be identified, reviewed, and eliminated.

Yet living organisms are historical structures: literally creations of history. They represent, not a perfect product of engineering, but a patchwork of odd sets pieced together when and where opportunities arose. (François Jacob 1977 – *Evolution and Tinkering*, p. 1166)

Definition

In broad evolutionary terms, a by-product is a characteristic of an organism that evolved simply because it happened to be structurally

and inextricably associated with an adaptation via historical constraints. As opposed to adaptations, evolutionary by-products are not the primary targets of natural selection. They have no functional design: they did not originate as solutions to adaptive problems. They only come about through the correlated selection of adaptations, and not because they were, themselves, *originally* selectively advantageous (i.e., during the period of evolution of the phenotypic trait under study). I will further define three types of evolutionary by-products, namely, spandrels (i.e., fitness-neutral by-products of adaptations), fitness-enhancing co-opted adaptations (i.e., exaptations Type 1), and fitness-enhancing co-opted spandrels (i.e., exaptations Type 2).

Introduction

A primary goal in evolutionary science is to determine whether a given phenotypic trait is an adaptation, a by-product of naturally selected features (i.e., spandrel, exaptation Type 1, or exaptation Type 2), or a residue of noise – or the result of a sequential combination of these products over evolutionary time. Among all these products of evolutionary processes, the first one has received the most attention, whereas the evolutionary significance of the others tends to be misunderstood and underestimated. After defining each of these concepts, I will highlight some common terminological confusions associated with the claims that a trait belongs to one of these categories. I will discuss the reliability and validity of such claims, particularly for behavioral and psychological characteristics that do not leave systematic traces in the fossil record. I will review some of the conceptual and methodological tools that allow researchers to distinguish among different evolutionary products and to test “evolutionary by-product” hypotheses. Moving away from a purely adaptationist stance, I will use examples from various research disciplines (e.g., evolutionary biology, evolutionary psychology, evolutionary linguistics) to rehabilitate evolutionary by-products as truly representative of the historical essence of the process of evolution, rather than “best-of-a-bad-job,”

and often underrated, explanations one resorts to when functionalist hypotheses have failed to be supported by the data at hand.

A Few Evolutionary Processes and a Range of Constraints on the Evolution of Adaptations

Five Main Evolutionary Processes

Biological evolution is defined as a change in allele frequencies and thus in the phenotypic distribution, within a population of individuals from a given species, across generations and over geological time. In the scientific community, there is a consensus on the various evolutionary processes or forces, which can cause such changes. These include (1) mutations, defined as random errors occurring during DNA replication and generating new genetic variants; (2) genetic recombination, defined as the rearrangement/reshuffling of DNA sequences during meiosis by a series of breakage; rejoining and copying of chromosome segments; (3) gene flow, defined as the transfer of alleles from one population to another through the migration of individuals that carry those gene versions; (4) genetic drift, defined as the variation in the relative frequency of different genotypes because of the random sampling of individuals from one generation to the next due to chance events, whose effects are stronger in smaller populations; and (5) natural selection, defined as the differential reproductive success of individuals contributing to the gradual and generally directional shaping of phenotypic traits, due to heritable phenotypic variation (Ridley 2004). It is noteworthy that sexual selection is considered a mode of natural selection in which assortative/disassortative (i.e., nonrandom) mating is defined as the tendency for individuals to select mates that are more similar/dissimilar to themselves in terms of phenotypic characteristics than would be expected by chance. To some extent, all these evolutionary processes create changes in the biologically inherited traits (i.e., genotype) of a population of individuals over successive generations. It is also widely acknowledged that natural selection is the primary driver of evolutionary change of organisms in response

to the external pressures of the ecological environment and the only evolutionary process that can produce adaptations (i.e., integrated features designed to solve particular fitness-related problems in the ancestral past; Williams 1966).

Yet, beyond these broadly accepted notions, the literature on evolutionary theory has long been the battlefield of heated debates, including clashes about the relative power of natural selection and the relative ubiquity of adaptations (e.g., Gould and Lewontin 1979; Sterelny 2001). Indeed, all evolutionary scholars agree that Darwinian evolution cannot be reduced to the following sequence of events: a series of random genetic mutations bringing about a large pool of phenotypic variants, gradually winnowed away by the exclusive action of external selective pressures, and necessarily leading to adaptations. Such a simplistic and deterministic view would correspond to a null model assuming that organisms evolve only in response to ecological factors, independently of internal factors (i.e., in the absence of constraints). We know this model is not tenable. Even Darwin and scientists who may be characterized as early ultra-Darwinists (e.g., Thomas Henry Huxley) or neo-Darwinian hardliners (e.g., Daniel Dennett, Richard Dawkins, and Steven Pinker) have never denied the importance of multiple constraints that limit the range of phenotypic outcomes of selection (but see Olson 2019a, for a false dichotomy between adaptation and constraint; see also Antonovics and van Tienderen 1991, for the claim that most studies of constraints are limited by the lack of a clear null hypothesis).

Constraints

In evolutionary parlance, a constraint is a causal mechanism – originating from the internal organization of the system under study – that reduces the range of possible phenotypes available for sorting by the selection process based on external pressures (Raff 1996). In other words, constraints usually refer to the limited ability of natural selection to break or modify the structural correlations among an individual's constitutive characters. A constraint prevents directional selection from continuously changing any phenotypic trait and

always creating more optimally designed adaptations (i.e., the highest fitness-enhancing phenotype cannot be reached). By setting boundaries to phenotypic variability, a constraint produces stabilizing selection, lessens the evolutionary response of phenotypic traits to external selective factors, limits the adaptation of the system to its ecological environment, and holds powerful reins over possible evolutionary pathways (Schwenk and Wagner 2004).

There are many types of constraints (e.g., time-lag effect, available genetic variation, costs involved in the construction of adaptations; Dawkins 1982), and the most relevant type to account for evolutionary by-products is referred to as historical constraints. Indeed, living organisms are not blank slates on which natural selection would optimally design new traits but historical structures with highly integrated body plans; their building blocks are not independent entities but interrelated packages of features that emerged from historically contingent events associated with the tinkering process of natural selection (Jacob 1977). Therefore, the evolutionary history of a lineage is deeply entrenched into the structure of its constituent taxonomic units, channeling their respective phyletic heritages, delimiting their pathways of development, and restricting modes of changes in their general architecture. This is why historical constraints on the evolution of organisms often include phylogenetic and developmental constraints but also structural, architectural, anatomical, morphological, geometric, allometric, pleiotropic, and epigenetic constraints (Antonovics and van Tienderen 1991). Historical constraints are found at different levels of internal organization of a biological system, including the genomic, organismic, or social levels (Thierry 2013).

From this perspective, organisms and their suites of phenotypic traits are not puppets with infinite potential for change because there are tight historical constraints on their optimal designs. Sometimes, there is simply no way to get there from here. According to Buss et al. (1998, p. 539), “[a]daptations are not optimally designed mechanisms. They are better described as jerry-rigged, meliorative solutions to adaptive problems

constructed out of the available materials at hand, constrained in their quality and design by a variety of historical and current forces.” In short, natural selection is not the only and all-powerful force of evolution, and adaptation is an onerous concept, just one among other evolutionary products (Williams 1966).

Five Main Products of Evolutionary Processes and Constraints: The Key Role of Causal History

There are five main products of the aforementioned evolutionary processes and constraints, namely, adaptations, co-opted adaptations (i.e., exaptations Type 1), spandrels, co-opted spandrels (i.e., exaptations Type 2), and residues of noise (please see Table 1 for general definitions and characteristics of these concepts; see also Linde-Medina 2017, for an extended “taxonomy of non-fitness”).

Adaptation

The term “adaptation” refers to both the *process* by which natural selection modifies a trait that facilitates the propagation of a (set of) gene(s) and the *end product* (i.e., the trait itself) that has been designed by this process. Strictly speaking, an adaptation (*sensu product*) is a trait that owes its existence to its causal history (i.e., because it was favored in the past by natural selection), regardless of its current usage or role. According to Sober (2000, p. 85): “Characteristic *c* is an adaptation for doing task *t* in a population if and only if members of the population now have *c* because, ancestrally, there was selection for having *c* and *c* conferred a fitness advantage because it performed task *t*.”

The primary usage that caused the adaptation to evolve is called a “function.” The function of an adaptation was the fitness benefit that led to the adaptation being favored by natural selection. Therefore, inferring the function of a trait consists in making a claim about why this trait came into existence during its period of evolution, and not what this trait performed later or currently does. This is why evolutionists and philosophers insist

on the terminological distinction between an “adaptation” and an “adaptive” trait (Burian 1983). They argue that these two concepts answer two questions that refer to two different temporal stages in the evolution of a trait, namely, what was the trait’s primary usage (i.e., its function) that favored its selection when it *originally* emerged in the ancestral past (i.e., the trait as an adaptation) and what was (*later*) or is (*currently*) the trait’s fitness-enhancing contribution (i.e., the trait as being adaptive).

Even though many traits are both adaptations and adaptive, the two terms are not interchangeable. A trait may be adaptive without being an adaptation. Indeed, a trait could, at any point in time, (have) become useful in performing task *t* and as a result (have) increase(d) the fitness of its bearers, even though the trait in question was not originally selected for this usage; for example, it might have arisen through one (or the combined effect) of the aforementioned nonselective evolutionary process(es), such mutation, genetic recombination, gene flow, or genetic drift. Conversely, a trait may be an adaptation without being adaptive. Indeed, a trait that was originally favored by natural selection to serve a particular function could, at any point in time, and if the environmental conditions change, lose its positive correlation with the survival rate or reproductive success of its bearers. Therefore, adaptation and adaptiveness are not synonymous because the definition of the former is history-laden, whereas the latter term does not speak about the evolutionary history of the trait. Historical causes and constraints are also at the core of the three main evolutionary by-products of naturally selected traits, namely, spandrels, exaptations Type 1, and exaptations Type 2.

Spandrel

Spandrels are fitness-neutral by-products of adaptations. Therefore, spandrels are *selected* (i.e., they arise through natural selection), but not *selected for* by-products of *selected for* phenotypic traits. Like other evolutionary by-products, spandrels have no functional design: these traits did not originate as fitness-enhancing solutions to ancestral adaptive problems *during* their period of

Evolutionary By-Products, Table 1 Definitions and characteristics of five products of evolutionary processes.

Name of evolutionary product	Adaptation	Evolutionary by-products			Residue of noise
		Exaptation Type 1 (aka: Co-opted adaptation)	Exaptation Type 2 (aka: Co-opted spandrel)	Spandrel	
Definition	Inherited and reliably developing trait that came into existence through natural selection because it helped to solve a specific problem of survival or reproduction better than alternative designs existing in the population during the period of their evolution	Trait arising from a preexisting adaptation whose original structure is subsequently co-opted for a new fitness-enhancing usage (i.e., effect) but without being modified by natural selection for this effect	Trait arising from a preexisting spandrel whose original structure acquires a fitness-enhancing usage (i.e., effect) without being modified by natural selection for this effect	Unselected(-for) and fitness-neutral by-product of an adaptation resulting from historical constraints, and arising as a necessary and functionless side effect of an adaptive design	Trait shaped by random effects resulting from forces such as chance genetic events during the development, or sudden and drastic environmental changes
Evolutionary process(es) causing the trait to evolve	Natural selection	Natural selection operating on preexisting adaptation	Natural selection operating on preexisting spandrel	Natural selection operating on original adaptation that is coupled with spandrel	Genetic mutations, genetic recombination, gene flow, genetic drift
Fitness-enhancing <i>during</i> the period of evolution of the trait?	Yes	No	No	No	No
Fitness-enhancing <i>after</i> the period of evolution of the trait?	Possibly (but not necessarily)	Yes (aptation)	Yes (aptation)	No (non-aptation)	No
Characteristic of the usage causing the trait to evolve	Primary	Secondary	Secondary	Not applicable	Not applicable
Name of the usage causing the trait to evolve	Function (in the historical sense)	Effect (i.e., later/current utility)	Effect (i.e., later/current utility)	Not applicable	Not applicable

evolution. Unlike other evolutionary by-products, spandrels did not acquire any fitness-enhancing role at any point *after* their period of evolution: these traits have never been, and are still not, adaptive. Spandrels have no, and never had any,

function and effect. Even though a spandrel was not, itself, selected, it evolved through a process of natural selection operating on the original adaptation that was structurally and necessarily coupled with the spandrel via historical

constraints. The inextricable structural connections between adaptations and spandrels can be explained by a number of biological mechanisms, including pleiotropy (i.e., genetic effect of a single gene on multiple and seemingly unrelated phenotypic traits in an organism) and linkage disequilibrium (i.e., nonrandom association between allelic variants at different loci within a population due to the history of recombination, mutation, and selection in a genomic region).

In a seminal paper aiming to combat pan-adaptationism – and its “just-so stories,” overestimating the number of adaptations in any organisms and erroneously attributing functions to any traits – paleontologist Stephen Jay Gould and geneticist Richard Lewontin introduced the term *spandrel* into the evolutionary literature (Gould and Lewontin 1979). In architectural terminology, a spandrel (or a pendentive) refers to the two-dimensional (or three-dimensional) and roughly triangular space that unavoidably appears between the tops of two adjacent round arches and the ceiling of a building (or the domed roof of a church). The arches are adaptive features that were designed to serve the function of supporting the ceiling/dome. However, spandrels are not adaptive features; they are the results of structural constraints and come about as inevitable and functionless side effects of the design of the building. “Spandrels [...] are necessary architectural by-products of mounting a dome on rounded arches” (Gould and Lewontin 1979, p. 581). Spandrels would not exist without arches (i.e., their adaptive counterparts). Even though the use of the term “spandrel” in evolutionary biology/psychology is relatively recent, the concept might go back to Darwin’s (1859/1964, p. 5) notion of “correlation of growth” (Gould 1997). It is beyond the scope of this review to further venture into terminological and conceptual debates. However, it is noteworthy that Gould and Lewontin’s (1979) influential critique of the adaptationist program has been itself heavily criticized by evolutionists, architects, and philosophers for (1) overstating the role of constraints in evolution (Rose and Lauder 1996); (2) mistaking spandrels for pendentives, which might not be the only structural solution possible

to mount a dome on top of arches (Houston 1997); and (3) discounting the argument that pendentives could be adaptive if they were “chosen from a set of equipossible alternatives largely for aesthetic reasons” (Dennett 1995, p. 274).

Despite the initial appeal and the potentially revolutionary implications of the spandrel metaphor, it is clear that the adaptationist program has not been shaken to the core over the past 40 years. Why not? According to Olson (2019b), the answer is simple: Current evidence of true biological/psychological spandrels is (at best) rare, anecdotal, limited to a few species, refractory to empirical testing, and even the handful tractable cases remain controversial. Let me examine these issues one by one.

First, Gould (1991) promised “spandrels by the thousands” (p. 58): “The number and complexity of these spandrels should increase with the intricacy of the organism under consideration. In some region within a spectrum of rising complexity, the number and importance of usable and significant spandrels will probably exceed the evolutionary import of the primary adaptation” (Gould 1997, p. 10754). However, a thorough literature review yields only a few examples of undisputed spandrels, most of them being morphological phenotypic traits: (1) the human chin originated as an unselected but necessary structural side effect of the selection for reduced mandibles in modern humans; (2) male nipples are functionless developmental by-products of the strong selective pressure on females to have functional nipples, and both sexes inherit these anatomical traits because of shared developmental pathways; (3) likewise, human female orgasm is largely considered a nonadaptive developmental collateral to the selection on male orgasm; (4) the extremely masculinized genitalia (often referred to as “pseudo-penis”) of female spotted hyenas are regarded as a nonselected but inevitable by-product of the selection for androgen-mediated aggressiveness that gives adult females a competitive advantage in the specific social system of this carnivore species; and (5) the umbilicus, defined as the axially aligned and hollow cone-shaped space within the whorls of a coiled mollusk shell, is a necessary and generally nonadaptive

structural side effect of winding a tube around an axis (Frank 1997; Gould 1997; reviewed in Olson 2019b).

Second, even much-cited examples of spandrels have not been empirically studied in detail in the primary literature; instead, they tend to be found in the secondary literature and are based on the authors' intuition (Olson 2019b; but see Frank 1997; Raia et al. 2010, for two notable exceptions). Third, spandrels appear to be idiosyncratic and sporadic in their phylogenetic distribution, making these traits non-amenable to cross-species comparative study – which is one of the most powerful methodological tools to explore the origins and evolution of biological features. Fourth, many spandrels are intractable to the hypothetico-deductive model and empirical methods. Buss et al. (1998) claimed that “Without specifying the origin of the adaptation that produced the by-product [...], the hypothesis that something is a spandrel generally cannot be tested” (p. 542). According to Olson (2019b), this failure is due to the persistent problem of “trait delimitation”: Spandrels do not represent “traits” or “parts” that could respond quasi-independently (i.e., as an almost atomized/discrete organismal unit) to natural selection. In Olson's (2019b) terms: “True spandrels are not things but simply spaces left over between things” (p. 63). Fifth, on closer examination, some often-cited examples of so-called spandrels turn out to be initially unselected traits capable of being subsequently put to use (i.e., simply misapplied synonyms for a particular type of exaptation).

Two Main Types of Exaptation

In 1982, paleontologists Gould and Vrba addressed a question that was not properly answered by most evolutionists: “What is to be done with useful structures not built by natural selection for their current role?” (p. 6). To avoid conflating a trait's current usage with its historical origin, they coined a new term that was apparently missing in the evolutionary science of organismal design, including its intricate fit between form and function: “Exaptation.” The term “aptation” comes from the Latin *aptus*, which means “fit,” and designates any trait that currently enhances

the fitness of its bearer, regardless of its evolutionary genesis. If the trait was originally designed and selected for this current usage (i.e., *ad-* in Latin, which means “toward”), it is an “adaptation.” If the trait was not originally designed and selected for this current usage, but owes its fitness-enhancing capacity to features present for other reasons, and is therefore *aptus* “by reason of” or “as a consequence of” (i.e., *ex-* in Latin) its form, it is an “exaptation.” The prefix *ex-* indicates that the trait's quality of being *aptus* is posterior to its origin. Therefore, an exaptation is one of the aforementioned examples of traits that are currently adaptive without being adaptations.

Exaptations capture four essential notions inherent to biological, psychological, and cultural evolution. First, a preexisting trait, including one that has evolved via natural/cultural selection, can be put to (a new) usage through a process called “co-option” or “co-optation” (i.e., functional recycling of ancestral structures), based on historical contingency (i.e., changing selective pressures and structural constraints). Second, because usage does not always precede form, the current usage of a structure cannot be used as a default explanation of the past origin and evolutionary history of that structure. Third, a multitude of fitness-enhancing phenotypic traits were not originally built by natural selection for their later or current usages. Fourth, because the current (or recent) capacity of an exaptation to enhance fitness did not contribute to the original selection of this trait, the fitness benefit the trait is “exapted to” cannot qualify as a function. Just as the primary usage causing an adaptation to evolve is called a “function” (i.e., its original usage), the (secondary) usage causing an exaptation to evolve is called an “effect” (i.e., its later/current usage; Gould and Vrba 1982).

Exaptations occur in two main forms (but see Pievani's (2003) four meanings of the word). An exaptation Type 1 is a trait arising from a pre-existing adaptation whose original structure is subsequently co-opted for a new fitness-enhancing usage (i.e., effect) but without being modified by natural selection for this effect. If any further adaptive benefits are gained by the co-opted adaptation through structural

modifications of the original design via natural selection, then the trait becomes a “secondary adaptation” (Gould and Vrba 1982). Most complex phenotypic traits have probably undergone a long and tinkering-like process of primary adaptation (toward a fit for an original/first function), followed by a primary exaptation (in which the structure is recruited for an effect but to which it may not be perfectly suited), followed by a secondary adaptation (improving the performance of the exaptation for this new usage/second function), etc. A typical example of this chain of consecutive adjustments is the evolution of feathers. This morphological trait may have first arisen as a primary adaptation for thermoregulation in ground-dwelling/nonflying ancestral birds, then been co-opted as imperfect flight-producing structures (i.e., first exaptation Type 1), then structurally modified by natural selection to hone their flight-related properties (i.e., secondary adaptation), and then co-opted again but without structural modification, for use as water-shedders by extant long-legged wading birds stretching their wings out while foraging for fish (i.e., second exaptation Type 1). Other examples of hypothesized sequential co-options in other phenotypical categories include ritualized behavior patterns in various animal species, as well as the evolution of religious beliefs and linguistic components in humans. In addition to solving the problematic conflation of a trait’s current usage with its historical origin, Gould and Vrba’s (1982) new term (i.e., exaptation – Type 1) aimed to address the misleading and teleological flavor of a previous label which embarrassingly connoted foresight: “preadaptation.”

An exaptation Type 2 is a trait arising from a preexisting spandrel whose original structure acquires a fitness-enhancing usage (i.e., effect) without being modified by natural selection for this effect. In the architectural domain, a textbook example of co-opted spandrel is the display of Christian iconography that was secondarily added to the tapered spaces (i.e., spandrels) created between the archways and the domed roof of the basilica of San Marco in Venice (Gould and Lewontin 1979). In the biological domain, the aforementioned umbilicus is used by some

species of snails as a protective egg-brooding chamber (Gould 1997). The fontanelles (i.e., soft membranous gaps between cranial bones) and skull sutures caused by delayed cranial closure during embryogenesis probably first arose as spandrels of adaptive processes shaping the skeleton of various vertebrate taxa, including reptile and bird species that reproduce by oviparity, but may have been exapted by placental mammals to facilitate the parturition of large-headed neonates that need to pass through a narrow birth canal (Gould and Vrba 1982). As exemplified above, “exaptation is not incompatible with natural selection, but with an oversimplified representation of it” (Pievani and Serrelli 2011, p. 12). The concept of exaptation (Type 1 and Type 2) emphasizes the importance to consider the range of adaptive processes and products, beyond adaptation.

Residue of Noise

A residue of evolutionary noise is defined as a trait shaped by random effects resulting from forces such as chance genetic events during the development or sudden and drastic environmental changes. The evolutionary processes causing these traits to evolve include genetic mutations, genetic recombination, gene flow, and genetic drift, but not natural selection. To illustrate this type of traits and other evolutionary products reviewed in this paper, let us consider two examples, a naturally occurring one (the belly button) and a humanly designed artifact (the lightbulb).

First, the belly button is a morphological spandrel in placental mammals: it is a necessary and fitness-neutral by-product of a specific adaptation (i.e., the umbilical cord, naturally designed to provide food and oxygen to the developing embryo and fetus). The particular shape of an individual’s belly button can be considered a residue of noise. Hypothetically, one could imagine a cultural scenario in which a pierced belly button would give its human bearer a survival/reproductive advantage in certain ethnic groups, making this modified evolutionary by-product a co-opted spandrel (or an exaptation Type 2). Second, the incandescent lightbulb is an adaptive design comprised of features (i.e., the tungsten filament

surrounded by a high-vacuum atmosphere contained within an all-glass envelope) that were originally selected/engineered to serve the function of light production. However, lightbulbs also generate heat as a by-product of light. In most cases, heat is a useless side effect of light production (i.e., a spandrel). In some cases, the heat generated by the lightbulb can be co-opted and serve as a heating system (i.e., an exaptation Type 2). Finally, the minor imperfections in the smoothness of the glass envelope resulting from insignificant imprecisions during the manufacturing process, but that have no bearing on the functioning of the lightbulb, can be considered residues of noise.

Testing the Hypotheses That a Trait Is an Adaptation or an Evolutionary By-Product

The traditional approach to testing “functionalist” and “non-functionalist” hypotheses is based on Williams’ (1966) argument that demonstrating adaptation carries an onerous burden of proof. In other words, a trait can be confidently identified as an adaptation on two mandatory conditions: (1) it met the strict evidentiary requirements of a special design, and (2) a set of alternative hypotheses (i.e., exaptation Type 1, exaptation Type 2, spandrel, residue of noise) have been systematically considered, have been rigorously tested, and have unequivocally failed. To achieve these goals, the conceptual and methodological toolkit of evolutionists include a number of evidence-based criteria grouped into different categories, namely, (1) *phylogenetic*, broaden cross-species comparisons and further the cladistic information pertaining to the phenotypic trait under study to reconstruct evolutionary scenarios about step-by-step changes over time; (2) *physiological*, acquire a deep and integrated view of the ontogenetic, allometric, genetic, and epigenetic underpinnings of this trait to provide an “evo-devo” perspective to the problem; (3) *intraspecific structural variability*, compare, across individuals of the same species, the structural variability within a pair of phenotypic traits that are

developmentally and evolutionarily linked but vary in their functional constraints – the prediction being that the adaptation should be less structurally variable than the corresponding spandrel/exaptation, because there was no direct selective pressure on the latter; (4) *structure-usage correspondence*, explore the multiple usages of a given structure, as some may be original functions and others may be subsequent effects, and the multiple structural options for a given usage to test the strength of the structure-function correspondence necessary for a strictly adaptationist hypothesis; (5) *(reverse) engineering* or *optimal design*, conduct biomechanical experiments and formal mathematical simulations to evaluate the supposed fitness-enhancing values of more or less altered/constrained phenotypic structures; and (6) *fitness/utility maximization*, test the actual correspondence between structure and function/effect/benefit in living and fossil species in their respective current and reconstructed ancestral environments (Andrews et al. 2002; Pievani and Serrelli 2011).

However, testing hypotheses about “adaptations” versus “evolutionary by-products” is a daunting task, for a number of interrelated reasons (Buss et al. 1998). First, these hypotheses should lead to the formulation of clear, specific, and testable/falsifiable predictions. Second, in principle, the five aforementioned evolutionary products are compatible and not mutually exclusive. They can even all play a role in explaining the evolution of a given phenotype. Evolutionists must demonstrate empirically the respective roles and causal sequence of action of different products in the evolutionary history of a trait. Third, investigating the emergence, diffusion, or maintenance of an adaptation, an exaptation Type 1, an exaptation Type 2, or a spandrel, consists in asking different questions, based on different assumptions (e.g., gradualist versus saltationist views on the speed of evolutionary changes), involving different schools of thought (e.g., weak versus strong adaptationism) and requiring different research techniques. Fourth, some traits (e.g., behavioral and psychological characteristics) are not readily amenable to phylogenetic inquiry

because they are (1) poorly represented in the fossil record, (2) variable across individuals, and (3) plastic within individuals, now and (presumably) in the past. Fifth, due to historically contingent, and thus unpredictable, structural constraints, an adaptation could show suboptimality and fail fitness maximization tests (i.e., a “false-negative” case). Sixth, there are no general rules that could be applied across phenotypic traits, species, and environmental conditions; testing “evolutionary by-product” hypotheses must be done on a case-by-case basis. Seventh, this line of research is still crippled by pervasive cognitive biases: some scientists remain vulnerable to teleological stories, and too many functionalists believe that finding a by-product explanation for the evolution of a trait devalues this trait, as if finding an adaptation was more scientifically appealing than finding an evolutionary by-product.

Conclusion

For decades, Williams (1966), Gould (1997), and their evolutionist and developmentalist followers have championed Darwinian pluralism by highlighting the variety and significance of evolutionary by-products and advocating for an extended taxonomy of fitness (Pievani 2003; Stump 2010) and non-fitness (Pigliucci and Kaplan 2006; Linde-Medina 2017), including aptations (i.e., fitness-enhancing traits, such as adaptations, secondary adaptations, and exaptations), non-aptations (i.e., fitness-neutral traits, such as bonuses, postaptations, and spandrels), and malaptations (i.e., fitness-reducing traits, such as maladaptations, malexaptations, and maladaptive spandrels). With their transcendent “spandrel” metaphor (Gould and Lewontin 1979) and their concept of “exaptation” as a modern and stronger rendition of Darwin’s notion of preadaptation (Gould and Vrba 1982), a few insightful structuralists (e.g., paleobiologists and geneticists) have sought to challenge the fields of evolutionary biology/psychology by encouraging their functionalist counterparts to take evolutionary by-products

seriously, consider non-adaptationist hypotheses diligently, focus on the problem of trait delimitation, and clarify the internalist/externalist dichotomy.

As a result of their heuristic approach, research on organismal form and function has been profoundly transformed. Gould’s pluralistic perspective on evolutionary theory, grounded in the interwoven concepts of constraints, spandrels, and exaptations, is now part and parcel of “textbook” evolutionary biology/psychology (Andrews et al. 2002; Ridley 2004). In their seminal paper about exaptations, Gould and Vrba (1982) reminded us about the very nature of our quest: “As evolutionists, we are charged, almost by definition, to regard historical pathways as the essence of our subject” (p. 7). The concepts addressed here, namely, adaptations and three main types of evolutionary by-products (i.e., exaptations Type 1, exaptations Type 2, and spandrels), as well as their fitness-enhancing or fitness-neutral contribution (i.e., functions, effects, or lack thereof), are *historical* in nature and were treated as such.

Definition

Evolutionary change is the heritable change in populations and species over time, due to mechanisms such as natural selection, random genetic drift, and sexual selection.

Introduction

Evolution is heritable change over time, through which species change, diverge, and sometimes create new lineages. “Evolution” and “natural selection” are often used interchangeably, but the two are distinct: evolution is the pattern, and natural selection is one of many mechanisms that *cause* evolution. Under natural selection, organisms which are better adapted to their environment have more (or healthier) offspring, so their traits are more often passed on to future generations. In this manner, natural selection drives evolution. However, other mechanisms can also drive evolution, such as random genetic “drift,” or random changes in genes and traits over time, artificial selection by humans for human-desired traits in other organisms, and sexual selection for traits that increase an individual’s chance of mating. All of these mechanisms operate by impacting heritable variation to drive evolution.

Evolutionary change requires that individuals vary in ways that are passed on (in whole or in part) to their offspring. Although the observation of heritability in nature (“like begets like”) is sufficient for some evolutionary inquiry, scientists now have a rich understanding of the primary mechanism of heritability: genetics. All life on earth is based on genetic code that is carried within cells and translated into observable traits. Humans, sea horses, mushrooms, the common cold virus, and more all reproduce by passing genetic material in the form of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) on to their descendants. Every organism is the sum of interactions of their genes (functional stretches of DNA or RNA) with their environment, resulting in their phenotype, i.e., the set of all traits that are expressed in a given environment and are seen by other individuals. In addition to genetics, “epigenetic” modifications (changes to the ways genes are expressed, such as conditional switches that turn genes “on” or “off”) can also be heritable and thus can play a role in evolution.

Mutation generates variation in the genetic code due to (i) random errors in our cellular machinery or (ii) environmental influences (induced errors). Genetic mutation can translate

into heritable differences in an organism’s observable traits, or phenotype, with neutral, positive, or negative effect on the organism’s fitness. While mutation, and thus differences between organisms’ genetic code, is the basis of variation, several higher-level factors contribute to variation. Gene flow between separated populations of the same species can also induce variation, and recombination during sexual reproduction reshuffles genes and their associated traits.

Scientists research evolutionary change by examining the fossil record, interpreting genetic evidence in the present, inferring genetic pathways over time, modeling change, and performing real-time evolutionary experiments with model organisms such as flies, yeast, and mice. This wealth of approaches has contributed greatly to a scientific understanding of the causes and persistence of variable life on earth.

Evolution is popularly conceived as a stairway of progress – from simple to complex, from bad to good, and from animals to man. This is completely untrue. Rather, it is more like a tangled bush with connections, splits, divergences, and interlocking parts. Humans are merely a tiny tip at the end of a tiny branch on the gigantic “Bush of Life.”

Heritability

Genetics

Genes control heritable traits and are the units of heredity. “Genotype” refers to the genetic material in an organism, while “phenotype” refers to observable characteristics whether inherited or not. Phenotypes result from genes, from environment/behavior, or from the interaction of genes with the environment (often popularly written as “nature plus nurture”). Selection generally acts on phenotypes, but phenotypes are not directly transmitted from parents to offspring – genes are. A single human’s overall phenotype could include tall height, brown hair, brown eyes, interest in and success at computer science, preference for neutral-toned clothing, no memory for details, and great storytelling ability. As this example suggests, not all phenotypic characteristics are

heritable! Eye color is fully heritable from known genetic variants, but interest in computer science is determined in part by inherited talent but also in large part by one's environment growing up. This is one complication of evolutionary inquiry: there is not a one-to-one correspondence between traits we can observe and measure (phenotypes) and heritable units (genes) coded in DNA.

DNA, deoxyribonucleic acid, is a long thin molecule that contains the "code" which is translated into proteins, the building blocks of cells, tissues, organs, and ultimately our bodies (some viruses use RNA, rather than DNA, as their unit of heredity; it is debated whether viruses are truly alive). DNA has an iconic "double helix" structure, with chemical bases in the center surrounded by phosphate-sugar chains. The chemical bases are of four kinds, represented by the four letters A, T, C, and G (which refer to adenine, thymine, cytosine, and guanine, respectively). DNA is shaped roughly like a spiral ladder, and these four bases pair up with one another (A with T, C with G) to form the rungs while the outer bars are formed by phosphate and sugar. DNA is "transcribed," i.e., copied by the enzyme RNA polymerase into messenger RNA, a molecule similar to DNA, which is then "translated" into protein. DNA base pairs are grouped into sequences of three called "codons" which correspond to specific amino acids (or in some cases, "stop" codons signal a stop in translation). The third position of a codon is called the "wobble" position because base pairs in that slot do not always obey the pairing rules described above (A with T, G with C); further investigation of this important phenomenon is outside the scope of this article.

Genes are stretches of DNA, ranging between less than one hundred base pairs to over two million, that in essence code for a specific string of amino acids which in turn folds into a specific protein. Almost all human DNA is the same in every individual human (over 99%); thus, only a very small proportion of the genome comprises individual variation.

Genes sit in a specific place on "chromosomes," which are the dense threadlike packages of genetic information that cluster inside the nuclei of our cells. However it is worth noting that our nuclear

DNA – the DNA on chromosomes in the nucleus – is not the only DNA we have in our bodies. Most notably, mitochondria have their own DNA that is inherited from mother to child (since mothers' ova contain the cell organelles). Mitochondria have DNA because they were independent organisms which our ancestors "domesticated" and put to work inside our cells. Chromosomes consist of DNA coiled around "histones," a special type of protein that allows the supercoiled structure of DNA. Humans have 23 pairs of chromosomes (since we inherit 23 from our mother and 23 from our father). Twenty-two pairs are "autosomal" chromosomes, which conventionally are numbered from 1 to 22 from largest to smallest, while the 23rd pair consists of our sex chromosomes. These are the X and Y chromosomes that determine our biological sex (Other animals have different mechanisms of sex determination, such as temperature-dependent sex determination in some reptiles (Warner and Shine 2008).). Female humans have XX sex chromosomes, while males have XY chromosomes. Some autosomes may be familiar to you; for example, if an individual inherits three copies of chromosome 21 instead of the usual two copies, this is referred to as "trisomy 21" or "Down syndrome."

The place of a certain gene on a chromosome is called its locus. Genes can have multiple slightly varying forms known as alleles; these allelic differences code for many of the differences that separate humans from one another. For most genes, we inherit two copies (one from each parent); if you have two copies of the same allele, you are *homozygous* for that allele. If you have two different alleles, you are *heterozygous*. The ways in which the two different alleles interact determine your phenotype. Different alleles can be codominant, where both are expressed to some extent; they can be in a dominant-recessive relationship where only one copy of an allele is necessary for expression; or different alleles can be related in more nuanced interactions. For an artificial, simplified example, imagine that eye color is a trait coded by a single eye color gene. Assume that you can inherit either a blue or brown allele from your parents and that brown is dominant to blue. If you have two blue alleles, you have blue eyes; similarly, two brown alleles produce brown

eyes. But if you have blue and brown alleles, since brown is dominant to blue in this imaginary simplified scenario, you will have brown eyes. However, you could have a child with blue eyes, as long as (i) you pass your blue allele on to the child and (ii) that child inherits a blue allele from their other parent as well! This is an important principle: traits that are not expressed in a parent can nonetheless be genetically hidden only to be expressed in later generations (Most traits, including eye color, are much more complex than described here).

Crucially, DNA can replicate itself. This is the basis of life. When our cells divide, DNA is copied so that each cell contains a complete copy of our genetic code. During cell division, which is essential for growth, maintenance, and reproduction, DNA is “unzipped” and copied by molecules and enzymes dedicated to these tasks. Sometimes during this process of copying, our copying mechanisms make errors. A stretch of DNA that read AATC might get accidentally copied as AATG. If this mistake is not noticed and corrected by our cellular mechanisms, it will be preserved in that cell’s genetic code as a mutation. If that cell is a reproductive cell, the mistake could replicate to offspring. There are many kinds of mutations, which we will turn to below; this is one source of the variation that can drive evolution.

Note that in many cases, genetic mechanisms and inheritance are more complicated than described above. The full complexity of genetics is beyond the scope of this entry, but it is important to note several caveats. “Selfish” genes act as self-interested agents that seek to further their *own* reproduction (Dawkins 2016). Indeed, sometimes the conflicting “agendas” of genes result in ingenious mechanisms for violating traditional modes of inheritance (Burt and Trivers 2006). Genes can be “sex-linked,” expressed only in the phenotypes of one sex, or “incompletely penetrant,” whereby, for example, a gene is not activated unless certain environmental conditions are met. Further, the connection between complex traits and genes is an ongoing mystery that geneticists are solving on a case-by-case basis with large data sets and statistical inference.

Epigenetics

We used to think that the DNA code that is passed from parents to child is the only mechanism of heritability. However, we now realize that this is not the whole story. “Epigenetics” describes changes to our gene *expression*, prompted by life experience. Remarkably, some of these changes are heritable. Consider the following landmark study on the inheritance of learned fear (Dias and Ressler 2014). Mice were trained to associate a certain specific cherry-like scent – acetophenone – with fear. Every time the scientists flooded the mice’s cage with the scent, they delivered small mild shocks to the mice. When the mice reproduced, the babies knew to fear the scent of acetophenone *without ever having undergone training*. Somehow, the learned experience – fearing acetophenone – was passed on to the mice’s offspring. This was not associated with *genetic* changes. While the specific mechanism in this case is still a mystery, we know it must be due to epigenetic inheritance.

So what exactly is epigenetics? While scientists define this term in many different ways, epigenetics broadly refers to modifications that control how genes are *expressed*. A very large part of our genome is not genes but rather is specific stretches of DNA that regulate expression of genes. Recall that genes are expressed by coding for proteins which perform a variety of functions; “silenced” genes are no longer expressed as proteins, while “upregulated” genes are expressed at higher levels than usual (and “downregulated” genes do the opposite). In many cases, protein-coding genes are regulated by associated stretches of regulatory DNA or regulatory regions in the genome usually (but not always) near a particular gene. In other cases, stretches of DNA pick up “tags” or reconfigure their shape in ways that silence, upregulate, or otherwise affect expression. Epigenetics refers to external influences (e.g., environment or behavior) that modify expression of genes, leading, for example, to turning genes on or off or affecting the timing and levels of expression of genes.

For our purposes, we are most interested in heritable epigenetic changes. Two of the most

important such mechanisms are DNA methylation and histone modification.

DNA methylation silences genes through chemical binding. Specifically, methyl groups are added to the chemical structure of DNA; where methyl groups bind, genes tend to be *less expressed* or turned off. Methylation is very important in genetic imprinting, which is the way in which genes are “tagged” as coming from one’s mother or father (and have corresponding expression modifications). A notable example of imprinting in humans is seen in Prader-Willi and Angelman syndromes – clinically distinct disorders associated with multiple anomalies and mental dysfunction, both usually due to deletions in part of chromosome 15. Whether an individual has Prader-Willi versus Angelman syndrome depends on which parent transmitted the faulty chromosome 15 to the child.

Histone modification affects DNA packaging, which determines which regions are “exposed” to the cellular machinery of gene expression. Recall that DNA is wrapped around histone proteins – it is packaged in a particular way that, with the help of these proteins, influences transcription and translation (the steps of gene activation). The shape of the histone proteins and the way in which DNA interacts with and wraps around histones can change based upon environmental influences and can be inherited.

Scientists do not yet fully understand how histone modifications are heritable; however, several studies have begun to unpack the ways in which methylation patterns are preserved from parent to child. For example, methylation patterns reveal whether a chromosome originated from the mother or father. On a maternally derived chromosome, genes that represent paternal interests are methylated and thus silenced. This is an intriguing and tricky concept and a famous category of “genetic conflict”; in short, in many mammalian species, mothers and fathers have different evolutionary interests, which are expressed through epigenetic “imprints” on their child’s genome. Genomic imprintings, as it is called, is known to occur in fungi, plants, and animals—including humans. For example, in humans, mothers bear the child and thus have an

evolutionary interest in keeping the baby’s body at a reasonable size. Fathers, however, have an evolutionary interest in making babies as large and well-nourished as possible, thus extracting maximum resources from the mother’s body. In our genomes, we see many patterns of methylation around genes related to infant growth and maternal provisioning that clearly demonstrate these opposing genetic interests a parental tug-of-war (Moore and Haig 1991, Haig 1993).

Thus, epigenetic inheritance is an additional component of heritability. It is counterintuitive to people familiar with strict genetic heritability, but there is no doubt that epigenetic inheritance plays a role in fitness, variability, and reproduction; therefore, it is important to consider as part of evolutionary change.

Variation

For evolution to occur, organisms must have heritable variation. That is, individuals must differ from others in ways that can be passed on to their offspring. Variation in genes and thus in individuals comes about through three primary mechanisms: mutation, recombination, and gene flow. In all of these cases, differences in the genetic code are the basic level at which variation occurs; these differences can be encountered and arise through mutation in an existing population, sexual recombination, described below, or gene flow (the movement of individuals and genes between populations that have been genetically diverging).

Mutation

Mutations are changes in the genetic code of an organism. Mutations can be categorized in many ways, but the most important categories for our purposes are “germline” versus “somatic” mutations, because these categories determine whether or not a mutation is passed on to offspring. In order for mutations to be passed on to offspring, they must be present in the germline, such as a mother’s ova or father’s sperm in humans. Mutations in somatic cells, or cells of the body that do not pass on to offspring, therefore do not affect an offspring’s fitness.

Alleles are different *versions* of one gene. For example, ABO blood type is determined, very simply, by which alleles you have of the “ABO blood type” gene. You get one copy of the gene from your mother and one copy from your father. The possible alleles you could have are A, B, and O. If you have the “A” allele and the “B” allele, you are blood type AB. Alleles A and A or A and O produce blood type A and likewise for B. Finally, if you have alleles O and O, you are blood type O. These alleles vary among individuals, just as do all other alleles. Species tend to have allelic variation; that, in combination with environmental variation, is why we do not all look and behave the same! Identical twins have very little allelic variation, because they inherited the exact same copies of the same alleles from their biological parents. Thus, in general, differences between identical twins are driven by the environment and the ways in which the environment impacts gene expression. Studies of identical twins (Boomsma et al. 2002) have found a variety of intriguing and peculiar findings about which traits are inherited and which are primarily driven by environmental variation.

Different alleles are generated by mutation, which occurs for two reasons: first, as DNA undergoes the process of replication, it can make a mistake. Each time a cell divides, there is a chance for the DNA to be copied incorrectly – this difference is a mutation. Second, environmental factors can directly cause mutation. Chemicals, or certain types of radiation, can break down DNA to such an extent that our DNA repair processes cannot adequately fix the damage.

Mutations can be “silent,” “deleterious,” “beneficial,” or “lethal.” Silent mutations in the genetic code, such as redundant base pair substitutions, have no effect on the gene’s function. Proteins are built from amino acids, and DNA codes for amino acids – however, each type of amino acid can be generated by multiple DNA templates. A mutation can also be silent if it occurs in a stretch of DNA with no function (But have caution! For many years, we thought long stretches of DNA that were known as “junk” DNA did nothing. Really, they served important, if complicated, regulatory purposes.). Mutations without strong

effects, and ideally without any effects at all, can be used to calibrate “molecular clocks” (Ayala 1986); that is, when we are trying to understand how long ago a species diverged from another species, we can compare how many mutations each species has in nonfunctional regions (Ho and Larson 2006). This is better than looking at functional mutations, since selection can act on those and interfere with our perception of how much time must have passed. A fundamental assumption, required to use the idea of molecular clocks, is that DNA not under selection accumulates mutations at a constant rate.

Of all functional mutations, the majority are deleterious, or harmful to the fitness of the organism in which they occur. Studies of the model fly species *Drosophila melanogaster* indicate that about 70% of functional mutations – that is, mutations that change the protein coding of a gene – are deleterious (Sawyer et al. 2007).

Beneficial mutations confer some fitness advantage to their host organism. Sometimes, of course, we might not understand their benefit in today’s world! Once we are removed from the evolutionary context in which a mutation was selected for, it can begin to have negative consequences.

Many beneficial mutations come about when a stretch of genome is duplicated and passed on to offspring (but see Lynch and Conery 2000). In this case, there is genetic “redundancy” that gives a buffer for mutation. If something changes over the generations in one copy of the gene, it is less likely to cause trouble since the individual has another copy. A famous example of this is the evolution of trichromatic color vision in humans. Our ancestors used to have only two types of cones – long wavelength (red) and short wavelength (blue). There was a duplication in the gene coding for long-wavelength opsins, or light-sensitive proteins. Over time, the duplication allowed one set of long-wavelength opsins to diverge slightly and differentiate enough such that one set became specifically sensitive to green light and one to red light. Thus, we and two other primate groups independently evolved trichromatic color vision with our familiar sensitivity to red, green, and blue light through gene duplications (Dulai et al. 1999).

Indeed, *de novo* (new) gene duplications account for the largest family of genetic differences between humans and chimpanzees (Cheng et al. 2005). They are not always good – some are associated with human-specific diseases!

Finally, lethal mutations are simple and aptly named. They kill you.

Gene Flow/Migration

Mutations can arise in an existing population. However, another source of variation can come from interaction between populations. When individuals move from one population to another, they carry their genes with them. Thus, spatial migration is accompanied by genetic flow. Plants sending pollen far and wide, animals leaving their native ranges due to human pressures, and people migrating from place to place are all mechanisms of gene flow.

A related phenomenon is that of a “genetic bottleneck.” In this scenario, a population of a single species encounters a “squeezing” effect on their genetic diversity, as if they are flooding from a wide bottle into a narrow bottleneck, typically due to a very small population size. This can be caused by environmental disasters, such as an asteroid strike, flood, fire, disease that sweeps through most but not all of a population, or geographic separation (due to a small group populating, say, an island). If a small subset of a population becomes reproductively isolated and “founds” a new population, biologists call the resulting lack of genetic diversity the “founder effect.” Indeed, it is well understood that modern humans evolved in Africa and then spread to the rest of the world, encountering a genetic bottleneck on their way out of the continent. This is one reason why populations in (or descended from those in) Africa are far more genetically diverse than the rest of humanity.

Human impacts have had catastrophic effects on many species by decreasing their population size; overfishing, overhunting, and environmental destruction have led to mass extinctions and severe drops in genetic diversity.

Sexual Recombination

Children may look like a blend of their biological parents, but sexual reproduction does not actually

blend traits. Instead, genes “reshuffle” during the process of sexual reproduction. You are not a copy of either of your parents, nor are you perfectly in between. You wind up with combinations of traits that are not found together in either of your parents.

In sexually reproducing organisms (which are most animals, including humans), each parent passes on 50% of their genes to their child. In humans, for example, each individual sperm and each individual egg have been produced through a process that splits the parent’s genome in two. Most of our cells have 23 pairs of chromosomes – two chromosome 1s, two chromosome 14s, etc. and either two X chromosomes or one X and one Y chromosome. This process of creating eggs and sperm – which is known as meiosis – involves stages whereby these pairs of chromosomes pair up, exchange genetic material through “crossing over,” and then separate to be sequestered into eggs or sperm. Each sperm and each egg have 23 individual chromosomes, and these individual chromosomes are “reshuffled” versions of their parent’s chromosome pairs. Fascinatingly, some loci in a genome can manipulate meiosis to enhance their own transmission, such that they are found in more than 50% of germ cells. This is known as meiotic drive, and it is not yet known to what extent meiotic drive has influenced our evolutionary history.

Mechanisms That Drive Evolution

Natural Selection

Natural selection is the most commonly discussed mechanism of evolution, although it acts in concert with the other mechanisms described below to drive evolution. In short, natural selection requires variation, differential reproduction, and heritability. Organisms compete for resources and to reproduce; individuals vary in a population and pass on much of this variation to offspring; and individuals that are better adapted to local conditions pass on more copies of their genes to future generations. This is popularly termed “survival of the fittest.”

The building blocks of natural selection are variation within a population, differential reproductive success, and heritability. We have already seen that DNA makes up genes which are passed from parents to offspring; clearly, heredity is present. Further, variation is present in natural populations; this is clear from simple inspection, and the many studies linking genes to observable traits have demonstrated that variation is in large part heritable. Finally, “differential reproduction” refers to the fact that different individuals leave behind more or less offspring depending on how “fit” they are. Fitness is variably defined, but can be summarized as “an organism’s ability to survive and reproduce”. If populations were unlimited and every individual had equal chance to mate and leave behind equally fit offspring, the criteria of “differential reproduction” would not be met.

Artificial selection, or selection conducted by humans, is closely related to natural selection. Animal and plant breeding over the generations produces evolutionary change along metrics that humans care about – larger plants we want to eat, purebred dogs with arbitrarily preferable traits, and docile fat cattle for the slaughterhouse. It is the same exact mechanism as natural selection, except humans choose who gets to reproduce, rather than a harsh environment selecting for reproductive fitness.

Sexual selection is a special case of natural selection whereby individuals evolve traits that increase their chances of copulating with the opposite sex. This will be discussed in greater detail in the subsequent section “sexual selection.”

Since life has heritable variation and differential reproduction, natural selection is in effect. We see overwhelming direct evidence of natural selection in real time, in the fossil record, and in our genes.

Convergent Evolution: Strong Evidence of Natural Selection

The most powerful evidence for evolution by natural selection is the remarkable “convergence” of distantly related species who face similar selective pressures. That is, many species independently evolve similar traits because they are

useful and confer a fitness benefit within a specific environment. Sharks and dolphins share a similar body form even though one is an elasmobranch fish and one is a mammal the pressures of aquatic life led to selection for a torpedo-like body shape with fins. Vertebrates evolved wings for flight at least three times in birds, bats, and pterosaurs; further, mammals have evolved “gliding” body forms, with flaps of skin stretched between legs, in both the flying squirrels and the distantly related marsupial sugar gliders. While these examples are common, they barely scratched the near-unbelievable surface of convergent evolution over time and space.

Consider, for example, the phenomenon of “mammalian woodpeckers” (Cartmill 1974). In some areas of the world, there are no naturally occurring woodpeckers, and instead, mammal species evolved to fill the woodpecker “niche.” (“Niche” is a catch-all term describing an organism’s or species’ ecological role in the environment: e.g., what they eat and how they eat it). Today, there are two living mammal species who evolved to fill the woodpecker niche: the striped possum in Australia (*Dactylopsila trivirgata*) and the aye-aye from Madagascar (*Daubentonia madagascariensis*). These mammals are distantly related, and evolved completely independently on their respective islands. However, both have massive protruding incisors that they use to bore through and tear at wood, finely tuned ears that listen for grubs squirming within the wood, extremely elongate single fingers to reach into the wood and pull out grubs, and a uniquely reinforced skull to deal with the pressures of wood-boring (Cartmill 1974; McCoy and Norris 2012)! There are two additional proposed “mammalian woodpeckers” from the fossil record: *Hegetotherium mirabile*, an enigmatic notoungulate from South America, and *Yalkaparidon*, a marsupial from Australia. All of these species are only distantly related and yet evolved remarkably similar morphological adaptations to the specific niche of wood-boring; in other words, these animals evolved similar traits long after the split from their common ancestor. This is extremely strong evidence for the mechanism of natural selection (although the aye-aye

and striped possum are extremely similar, I am sorry to say that the aye-aye looks like a frightening demon while the striped possum looks like an adorable pet).

Selection at What Level?

The history of evolutionary biology is filled with arguments about the level at which selection operates (Okasha 2006). Does it operate on cells, genes, individuals, and species? An overview of this debate is beyond the scope of this entry. To briefly summarize, life is composed of many replicating “selfish” elements, perhaps most notably genes (Dawkins 2016) and individuals. Selection acts on phenotypes, and genes are the unit of heritability that are passed from parent to offspring. The correlation between gene and phenotype is not perfect, since the environment exerts an influence as well. Individuals who share a high proportion of their genes may be evolutionarily motivated to “help” each other; this is known as “kin selection theory” or “inclusive fitness” (Hamilton 1964). Over geologic time, paleontologists often talk about species-level selection, by which species diverge and emerge in response to fluctuating niches (Gould 2002). Some biologists will hear nothing of selection at a level higher than the gene.

To all levels of selection, there is some truth (Okasha 2006).

Genetic Drift

Genetic drift, unlike natural selection, is completely random and not determined by fitness. In any population, whether of people or parakeets, some individuals will be more successful by chance. They will leave behind more offspring – not because they are measurably “fitter” due to selected adaptations but because that’s the way the cookie crumbled. Without selective pressure on certain alleles, alleles drift in a random walk until one allele becomes “fixed” in the population – that is, until one allele is present in every individual in a population. If a population is small, such as in the case where a small subset gets cut off from the main population, or where a few members of a species populate an island, there is a higher chance that a certain allele will drift to fixation despite having a neutral or even negative effect.

There is much debate about whether selection or drift exerts stronger influence on evolution in a population. Are most traits there by chance or because they were selected for? Proponents of the “neutral theory” of evolution argue that much of evolution is caused by genetic drift and the random fixation of alleles. It is difficult to quantify the relative contributions of random drift and natural selection (for reasons such as “genetic draft,” see below), but both have demonstrably played a role in evolutionary change over time.

Genetic Hitchhiking (“Genetic Draft”)

Genetic “draft” is closely related to the phenomena of drift and selection. It is also called genetic “hitchhiking,” because it can be conceptualized as certain neutral or even deleterious alleles “hitching a ride” with beneficial alleles.

Genes recombine during sexual reproduction; however, the rate of recombination between genes varies depending on the distance between them. Further, the position of genes on a chromosome influences the likelihood that they will recombine and be separated from each other. If genes are close to each other, they are said to be “linked.” The nonrandom association of alleles at different loci is known as their “linkage disequilibrium.”

When two genes are linked, specific combinations of their alleles are almost always passed on and inherited together – as a unit. A few implications are obvious. First, if two genes are functionally related and become linked by chance, then there will be strong pressure for them to remain linked; for example, what if the gene for purple hair gets linked to a gene for preferring purple hair?

Second, a highly useful gene variant can be linked to a neutral or even deleterious gene. If they happen to be close together on the chromosome, that neutral or negative allele might sweep to high frequencies in the population just by “hitchhiking” along in the “selective advantage bus” driven by its neighbor gene. So when looking at genes in a population, it is not always safe to assume that a very common gene variant has a selective advantage. It may have “drifted” to high frequencies or been “drafted” by a neighbor.

Interpreting Evolutionary Evidence: Notes of Caution

Evolutionary “Spandrels” and Exaptations

In two landmark papers, Stephen J Gould, Elisabeth Vrba, and Richard Lewontin provided a fundamental note of caution when interpreting evolutionary evidence. It is tempting to look at a current organism with its suite of traits and think about why each trait is evolutionarily beneficial. However, scientists must be aware of “exaptations” or evolutionary “spandrels,” traits that either (1) evolved for a past purpose before being co-opted or (2) are just incidental by-products of adaptive traits.

Vrba and Gould coined the word “exaptation” to describe the following evolutionary truth: the current function of a trait does not always correspond with its historical function and origin (Gould and Vrba 1982). For example, we see that birds fly using feathered wings and think “Aha! Feathers evolved so that birds could fly.” However, a wealth of paleontological evidence calls this into serious doubt. Feathers evolved in dinosaurs long before flight evolved; they almost certainly aided in insulation and may have played a role in display, waterproofing, or defense (Prum 1999). Only later were feathers *co-opted* for the purpose of flight.

Related to “exaptations” are Gould and Lewontin’s evolutionary “spandrels,” a term inspired by architectural phenomena at the San Marco Cathedral in Venice (Gould and Lewontin 1979). This cathedral has a beautiful dome resting upon arches, and “spandrels” are the triangular windows between the intersecting arches. Usually spandrels are decorated ingeniously, as is the case at San Marco. If one just looks at the spandrels, they might be tempted to conclude that the spandrels were carefully and intentionally shaped and designed, and perhaps even that the rest of the building exists only to frame them. But in reality, spandrels are a necessary result of mounting a sphere on a dome; they are only an incidental by-product of the grander architectural scheme.

Similarly, it is tempting to look at an evolved creature, focus on a certain trait, and try to come up with its evolutionary purpose. But sometimes,

that trait is just a “spandrel” – an insignificant by-product of a trait that was truly evolutionarily significant. Indeed, Gould and Lewontin give as a primary example of spandrels the many peculiar processes in the human brain that we cannot fully understand (Gould and Lewontin 1979).

An Incomplete, Mysterious Fossil Record

Often in evolutionary history, we have incomplete evidence. Fossils give us clues about the past, and we can only see current life as a mere snapshot of the continuously changing spectrum of life and diversity.

The vast majority of life on earth is available to us only through fossil evidence. Some fossils are remarkably well-preserved, which allowed us to see, for example, the imprint of soft tissue, the outlines of dinosaur feathers, and more. Other fossils are frustratingly incomplete.

But even when scientists have a wealth of evidence, it is common to initially misinterpret fossils. For example, one of the most famous fossils of all time, the Tully monster (*Tullimonstrum gregarium*), was thought to be a mollusk or worm until it was recently found to be a vertebrate (McCoy et al. 2016).

This example illustrates the difficulty of correctly interpreting fossil evidence, even in the case of the relatively abundant Tully Monster. The history of human evolutionary biology is replete with sparse fossil finds, angry feuds, and misinterpretation. Many species of our hominin relatives were initially thought to be “deformed” examples of normal *Homo sapiens*, including Neanderthals and *Homo floresiensis*. Further, many of our hominin relatives are known by only extremely tiny scraps of bone and fossil. As Gould once wrote, “an old paleontological joke proclaims that mammalian evolution is a tale told by teeth mating to produce slightly altered descendant teeth.”

Evolutionary Change over Life’s History

The complete history of life ranges over four billion years, through alien worlds of sulfurous oceans beneath asphyxiating air, past iron-breathing bacteria and microscopic chimera, to arrive at last at our

familiar world of oxygen and ozone, forested valleys, and animals that swim, walk, and fly. Scheherezade could hardly have invented a more engaging tale. – Andy Knoll, *Life on a Young Planet*

A History of Life, Skewed Toward Vertebrates

The origins of life are uncertain, but scientists have generated some likely conditions and circumstances (Knoll 2015).

Life began in the ocean about 4 billion years ago, and it stayed there for some time. The last universal common ancestor (LUCA), the most recent type of organism from which all living things commonly evolved, was likely a thermophilic, anaerobic microbe (Weiss et al. 2016).

Life requires replicating molecules. The earliest such molecules were probably RNA, which is a nucleic acid similar to DNA that is capable of self-replicating. In short, certain RNA molecules can act as a polymerase which can replicate template RNA molecules by joining together individual RNA monomers, much like the current protein RNA polymerase. This process, self-replication, is crucial for life.

From the initial, murky moment that self-replication first came to be, three major branches of life evolved. The three domains of life are Bacteria, Archaea, and Eukarya. The first two, Bacteria and Archaea, lack a nuclear membrane; some members of Archaea are known to thrive in the most extreme environments, such as in volcanoes or at the bottom of the ocean. Eukarya are most familiar to us: we belong to Eukarya, as do fungi, plants, all animals, and some single-celled organisms such as amoeba. We eukaryotes are united by our possession of a nucleus within our cells – a tightly packed center of genetic code.

Millions of years ago, ancestral eukaryotes domesticated other single-celled organisms by enveloping them; these became our mitochondria. Mitochondria take care of certain respiratory functions of our cells. This phenomenon is known as endosymbiosis and has played many important roles in large evolutionary transitions. For example, endosymbiosis involving photosynthetic cyanobacteria and other organisms allowed photosynthesis to spread across the globe.

About 600 million years ago, the first animal species evolved. These mysterious early species are called the Ediacaran biota and are poorly understood. Some look like jellyfish, others look like worms, and some look distinctly different from anything living today; much of what we know about the enigmatic Ediacarans comes from fossil molds of the original bodies, so we have very little information about their ecology and evolutionary relationships. During the so-called Cambrian explosion, which actually lasted many years, most of the modern phyla of animals came to be (Briggs et al. 1992). The most famous fossil record of these species is the Burgess Shale, a rich deposit in Canada.

Four hundred million years ago, plants evolved from “green algae” (which had already domesticated cyanobacteria to enable photosynthesis). Then, 380 million years ago, vertebrates clawed their way onto land (in the form of amphibious critters). Arthropods were the first terrestrial animals by many millions of years, but we do not know exactly when they first crawled ashore.

Two hundred and fifty million years ago, the earth saw the most catastrophic extinction event in its history: the Permian Extinction, also known as the “Great Dying.” Somewhere between 81% and 96% of all life went extinct during this period; it took 30 million years for Earth to recover a comparable diversity of life. Both catastrophic and gradual processes led to the Great Dying, including volcanic eruptions, methane release from the sea floor, and increased anoxia and aridity worldwide (Sahney and Benton 2008).

Around 200 million years ago, in the wake of the Permian Extinction, sauropsids, archosaurs, and dinosaurs came to dominate land vertebrates. At this time, mammals were mostly small and insectivorous- but not for long.

Sixty-six million years ago, the Cretaceous period ended with a comparably minor mass extinction: the extinction of the dinosaurs (and many other animal groups). An asteroid collided with the earth which, in combination with other factors, wreaked havoc on the reptilian population. However, their descendants and relatives, birds, still cover the earth today. Indeed, from a formal phylogenetic perspective, birds are

dinosaurs. The extinction of the nonavian dinosaurs paved the way for mammals to stride forth from their nocturnal, small-bodied forms. Humans have recently become a particularly notorious ape.

Now, human actions are causing a global mass extinction greater and swifter than any before on record.

Human Evolution: Early Fossils, Close Relatives, and Genetic Traces

Four out of five animals on Earth are nematode worms – if all solid materials except nematode worms were to be eliminated, you could still see the ghostly outline of [the continents]. . . in nematode worms. – E. O. Wilson

And yet, here is a section dedicated to the evolution of man.

Humans evolved from apes. From fossils, we know that primates came to be about 55 million years ago, while genetic evidence (using molecular clocks) indicates that they first evolved 85 million years ago. Many, many species of *Homo* and relative genera flourished in Africa while our direct ancestors were evolving. Just a few of them emerged from Africa before our own migration out: *Homo floresiensis* (the hobbits), *Homo neanderthalensis* (the Neanderthals), and *Homo sapiens denisova* (the “Denisovans,” status as species or subspecies currently debated).

East Africa is rich with fossils of early hominins, particularly in the regions of Olduvai Gorge and Lake Turkana. Many of these fossils were found by the famous Kamoya Kimeu as well as Leakey family: Mary and her husband Louis, as well as their son Richard and daughter-in-law Meave. They were assisted by extremely capable fossil hunters and paleontologists.

Three of the most famous and important early fossils in this region are Lucy, Ardi, and the Nariokotome Boy. They are important because they are relatively complete, early relatives of ours who have human-like traits in combination with apelike traits.

Donald Johansen discovered “Lucy” (so named for the Beatles song “Lucy in the Sky With Diamonds”), the most famous hominid fossil of all time: Lucy lived about 3.2 million years

ago as a member of the small-brained, bipedal species *Australopithecus afarensis*. Lucy is also known as Dinkinesh, a translation of “you are marvelous” in the Amharic language. Lucy is famous for being a biped from so long ago and for indicating that bipedalism apparently preceded brain enlargement.

“Ardi” that is a hominid fossil more complete and older than Lucy was found first by a college student named Yohannes Haile-Selassie and uncovered and examined fully by Tim D. White. This was Ardi, a female individual of the species *Ardipithecus ramidus*, featuring opposable thumbs and *opposable big toes*, as well as an apparently bipedal gait. The species name comes from the words Ardi (“ground floor”) and the word ramid (“root”) in the Afar language – the point being that Ardi lived on the ground and lies at the root of all humanity.

Kamoya Kimeu, found the Nariokotome Boy: this fossil, formerly known as the Turkana Boy, is a young *Homo erectus* dating to 1.5–1.6 million years ago. It is the most complete early human skeleton known and had an extremely large brain and tall stature.

The East African fossils are incredible, but a recent, remarkable find brought Southern Africa back onto the map: *Homo naledi* was found in South Africa in the “Cradle of Humankind,” where 15 individuals were found in an extraordinary cave deposit, seemingly placed there intentionally. These fossils have not been dated due to the unique circumstance of their deposition, but the morphological characteristics make them strange chimera of near-modern features and highly “primitive” apelike features: human feet but apelike shoulders, human-like hands with apelike curved fingers, and a tiny brain. The full significance of this fossil find will be unraveled in years to come.

Our direct ancestors, archaic *Homo sapiens*, evolved sometime between 400,000 and 250,000 years ago. The “out of Africa” model describes how humans evolved to our modern form about 200,000 years ago, then left Africa, and displaced, interbred with, and perhaps outcompeted the other species of *Homo* already spread across the globe. It is certainly possible that

Homo sapiens left Africa multiple times. There may have even been a coastal dispersal of humans from the horn of Africa, leading to populations in Oceania and Southeast Asia.

Our closest living relative is the chimpanzee. We share between 95% and 99% of our genomes with chimps. However, we see genetic persistence of Neanderthal and Denisovan DNA in many populations of *Homo sapiens* today. This is because our ancestors interbred with these related subspecies of human; most human lineages of non-African origin have 1–3% Neanderthal DNA in their genomes (while a jawbone from an early modern human from Romania had 6–9% Neanderthal DNA (Fu et al. 2015)); many modern humans also have Denisovan DNA (Reich et al. 2010). For example, genes conferring resistance to high altitudes in Tibetans were derived from gene flow with Denisovans (Huerta-Sánchez et al. 2014).

Interestingly, human culture has driven genetic evolution (This gene-culture coevolution was recently demonstrated to exist in orcas as well, the first nonhuman species for which this has been conclusively demonstrated Foote et al. 2016). For example, a turn toward cultivating cattle for milk in Europe led to the evolution of human lactase persistence genes, genes that facilitate lactose digestion and allow adults to drink milk without adverse digestive upsets (Beja-Pereira et al. 2003).

The Evolution of Psychological Traits

When you light a candle, you also cast a shadow. –
Ursula K. Le Guin

All we ever see of stars are their old photographs. –
Alan Moore, Watchmen

Much of evolutionary inference comes from looking at shadows. This is true perhaps most of all for cognitive and behavioral traits, which tend to disappear in the fossil record (except for leaving “traces” such as footprints and stone tools) (In Chauvet Cave in Southern France, the footprints of a boy from 20 to 30,000 years ago appear alongside the footprints of a wolf with an apparently shortened middle digit, a characteristic of dogs (Garcia 1999). Was the

wolf domesticated? Did the boy and the wolf explore the cave together? Or are the footprint sets merely aligned by chance, separated by hundreds or thousands of years in real time?). Luckily for evolutionary psychologists, certain psychological phenomena have evident molecular, morphological, and genetic correlates which can be tracked by the fossil record and our own genomes.

Sensory perception is the tunnel between our brain and the world, and a wealth of evolutionary, molecular, and genetic evidence has unwound the perplexing spools of sight, smell, touch, and hearing (If we were so lucky to be pit vipers or vampire bats, we could also sense infrared; likewise for many other animals and their ability to sense electromagnetic fields). For example, we know about when our ancestors switched toward a primarily visual mode of life, because we see evidence that vision improved while our sense of smell got worse. Scientists have noted genetic signatures of color-sensitive cell evolution paired with the degeneration of olfactory ability. Similarly, we can interpret certain sensory and cognitive biases by better understanding how the visual system works; phenomena such as “color correction” (by which a red apple looks red whether it is in the bright sunlight or dark blueish light) are highly conserved across many vertebrate lineages.

Sensory perception is not the only evolutionary avenue to the brain: for example, certain genes have been tightly linked to higher cognitive functions. The defining human trait of syntactical language depends at least in part on a mysterious gene called *FOXP2*, which is necessary for proper speech and language. Scientists can trace the evolutionary history of *FOXP2* in the genomes of humans around the world, our close ancestors, and our extinct human relatives. Neanderthals, for example, shared our variant of *FOXP2* (Krause et al. 2007). We have discovered this gene’s function through characteristic language deficiencies in a family with many members who had an impaired copy of the gene; we have further expanded upon this knowledge with model organism experiments (Vargha-Khadem et al. 2005). Only two amino acid changes separate our human version of *FOXP2* from that of chimpanzees, our nearest living relative; despite this tiny

difference, chimpanzees do not have any communication system that we would call language.

The fossil record can even tell us information about the cognitive capacity of our ancestors and sister groups. Fossil endocasts of human brains – that is, the inside of preserved skulls of our human relatives – give us information about how large their brains were and sometimes even whether or not they had enlargement of certain regions associated with language processing, such as Wernicke’s Area and Broca’s Area (Jerison 2012). Braincases are fragile and are rare to discover in the fossil record, but they can reveal the brain volume of an extinct human and help us understand its relative cognitive abilities.

Finally, indirect correlates in the paleontological and archeological record provide clues to the nature of human cognition. For example, cave art and artistic engravings are associated with increasing creativity and complex psychology. Even more simply, tool use is associated with intelligence. Of course, humans are not the only toolmakers and users. For example, New Caledonian Crows (who live on a peculiar South Pacific island) are sophisticated toolmakers (With New Caledonia’s relative isolation, rich metal deposits, and friendly climate, one cannot help but wonder: is there an alternate world where intelligent crows dominate the globe?). But the existence of hominin-made tools in the fossil record tells us a bit about cognitive development and technological advances over time. When these tools are found in close company with actual hominin fossils, we can learn even more. The fossil record is filled with stone tools from our ancestors and our hominin sister taxa, including stone axes, stone choppers, stone flakes for cutting, and hammerstones. The oldest stone tools were long thought to be made 2.6 million years ago, in eastern Africa, by the aptly named *Homo habilis*. However, a wealth of tools found at Lake Turkana in Kenya date back even farther to 3.3 million years (which is prior to the evolution of the genus *Homo*). Thus, scientists think that these early tools may even have been *Australopithecus afarensis* or *Kenyanthropus platyops* (Harmand et al. 2015).

Finally, evolutionary psychology can draw upon behavioral and cognitive studies of extant

nonhuman animals. Most useful for these purposes are (i) our relatives, most notably great apes and other primates, and (ii) distantly related species who convergently evolved similarly enlarged brains, complex social behaviors, and sophisticated cognition. From our primate relatives, we have learned much about the evolutionary roots of primate social structure, behavior, cognition, and perception. For example, a study of monkeys who were introduced to a system of currency suggests that the roots of “loss aversion” (our exaggerated “dislike” for losses that exceeds the corresponding “like” for an equivalent gain) run deep in our evolutionary history (Chen et al. 2006). Cetaceans, elephants, corvids, and other large-brained animals have given us further information about *in what circumstances* and *along what pathways* complex cognition has arisen in evolutionary history. For example, with the notable exception of the short-lived, asocial, intelligent octopus, most animals who have convergently evolved large brains and complex cognition are social and long-lived.

Through fossil evidence (such as brain endocasts), archeological and paleontological records (such as cave paintings and tools), genetic history of genes such as the famous *FOXP2*, genetic and molecular studies of sensory perception, and comparative cognition studies of living organisms, we can begin to understand the evolution of our large, unusual brains.

Conclusion

Over time, species change and diverge under the influence of natural selection, genetic drift, and population effects such as bottlenecks. Scientists can learn much about the evolutionary history of extant organisms, and their relatedness to each other, by examining the fossil record and genetic evidence. Natural selection is a powerful force that has shaped our own evolution, and that of all living things. Natural selection does not select “good” traits; rather, it selects traits that allow organisms to survive and reproduce. Evolution is not a staircase describing the ascent of man;

rather, it is a complicated bush with myriad organisms adapted to myriad environments. Interpreting evidence to make evolutionary conclusions is difficult, particularly when scientists seek to understand complicated traits such as human intelligence, which have a spotty fossil record and complex genetic and environmental underpinnings. Nonetheless, no trait can be completely understood outside of an evolutionary framework. Understanding evolution can help explain where we humans came from, where we are going, and why the way we are. As Theodosius Dobzhansky famously wrote, “nothing in biology makes sense except in the light of evolution”.

Definition

Evolutionary clinical psychology, or evolutionary psychopathology, is the study of mental disorder from an evolutionary perspective. Evolutionary psychology, in general, studies primarily how the mind works, in its normal and universal state. Different evolutionary approaches consider both the conditions that mainstream mental health care and research have defined as abnormal or pathology, or offer evolutionary perspectives to how these conditions may be considered adaptive, or even how one may fundamentally understand what psychopathology is.

Introduction

Evolutionary clinical psychology is the study of mental disorder from an evolutionary perspective. This enterprise involves discussions of how to understand the human capacity for mental

disorder (Gilbert 1998; Nesse 2011), definitions of mental disorder (Wakefield 1992, 1999), and even adaptationist approaches to symptoms and disorders (Andrews and Thomson 2009). Evolutionary approaches to mental disorders have existed ever since Freud explained the Oedipus complex with a phylogenetic explanation. This early attempt was obviously incorrect, as the castrated young boy hardly could pass on his anxiety or his genes to later generations. Later functional approaches to anxiety, and a basic evolutionary understanding of attachment between mother and infant (Ainsworth and Bowlby 1991), became influential within mental health care. Throughout the years, there have been several attempts at providing mental health research with evolutionary underpinnings (Kennair 2003; McGuire et al. 1992). Alas, few of these have been successful in collecting the field or creating consensus for a shared metatheory (Kennair 2011). To some degree, there is also some tension in the field between evolutionary oriented clinicians and clinically interested academics, which most clearly comes to a head in discussions of the possible adaptive function of major depressive disorder (Kennair et al. 2017). The current chapter will address a few of the most relevant contributions and controversies of this field.

Defining Psychopathology: The Harmful Dysfunction Analysis

It is hard to clearly define the boundary between nondisorder and disorder, especially within psychopathology. An important reason for this is that mental disorders have both biological foundations and are at the same time value-based perceptions of what is considered “normal” and “abnormal.” From an evolutionary perspective, it is obvious that neither how many suffer, subjective experience of suffering, or physical sequela, provide good enough grounds for defining pathology. Disease can be common, and some evolved traits can be rare. In the Harmful Dysfunction analysis of mental disorders, Wakefield (1992) combines both the biological and the value-based aspect of mental disorders.

“Harmful” refers to social norms on what is considered good or bad for the well-being of people or societies. While “dysfunction” refers to an evolved function that fails to perform the function for which evolution designed it. Wakefield’s definition of psychopathology is one of the most influential contributions to mainstream psychiatric and clinical psychological theory. The problem, though, is obvious: It is possible in a specific culture at a specific time to agree on what is harmful, given social norms. However, that brings with it the problem that different conditions and morphs may be redefined as normal or pathology due to social changes. Further, we currently do not have a full catalog of evolved mental mechanisms and their normal functions. There might, therefore, be reason to argue for greater integration of evolutionary psychopathology with evolutionary normal psychology, also as a research paradigm (Kennair 2011). We need to know the normal functions of the mechanisms of the mind, in other words a comprehensive evolutionary psychology, to be able to define psychopathology as harmful dysfunction.

Life History Approach to Taxonomy

Recently, Marco Del Giudice (2014) made a thorough contribution to the conceptualization and taxonomy of psychopathology from an evolutionary psychology perspective. Based on his analysis on fast and slow life history, Del Giudice attempts to synthesize and integrate the underlying processes of psychopathology. The many different responses to his target paper reveal both support and skepticism – not least to the somewhat simplifying fast-slow dichotomy, but also to Del Giudice’s conceptualization of some of the specific disorders such as subtypes of OCD that involve fast lifestyle impulsivity (Kennair 2014). However, criticism of an explicitly formulated theory demands that one generates empirical tests. For example, Del Giudice’s taxonomy suggests that measures of life history strategies should predict depressive symptoms, and slow life history should predict more depressive symptoms than fast life history, at least for some subcategories of depression (Del Giudice 2014). Yet, again, this is testable, and will produce data. Ultimately, this

is, therefore, a major positive development of the field of evolutionary psychopathology.

Evolutionary Medicine: Why Does Psychopathology Exist?

Evolutionary perspectives are useful within medicine and clinical psychology because it helps us to think clearly about what symptoms are. Sometimes symptoms are defenses against disease, rather than a manifestation of disease itself (e.g., coughs, fever, and diarrhea). Nesse and colleagues (Nesse 2011; Nesse and Williams 1996) have been very clear about the aim of an evolutionary medicine approach to psychopathology: the aim of an evolutionary approach is to describe how evolved human nature and the human mind make us vulnerable to developing mental disorder. This is also Paul Gilbert's (1998) approach: the mind has constraints and is not perfect, and mental disorder may arise as a result.

A fundamental insight from evolutionary medicine and psychopathology is that natural selection does not care about our well-being. Whatever works for effective gene replication is what is selected for. That is not to say that selection does not construct brains capable of pleasure, but rather that evolution does not select for happiness as a goal in itself. The smoke-detector principle is a good illustration of this (Randolph M Nesse and Williams 1996). If you want to avoid fire in your home, its better to have sensitive alarms that sometimes go off inappropriately, but always go off when there is a fire. In the same way, evolution does not select for fear and anxiety mechanisms that protect individuals from worrying too much because anxiety feels bad. False alarms cost a few calories, but not reacting to a life-threatening situation is an evolutionary catastrophe.

The causal power of natural and sexual selection to design vastly complex machinery such as the human brain is awe-inspiring. Nevertheless, it would be terribly naive to claim that all symptoms of mental disorders (e.g., psychosis, autism, and major depression) always are the products of underlying evolved adaptations. Despite the power of selection, disruption of evolved design

happens for environmental reasons, such as modern humans sleeping too little, eating too much sugar, and doing too little exercise. And dysfunctions also happen for genetic reasons, such as deleterious mutations constantly eroding evolved design. We will look at these factors in the problems section below.

The opposing view to the Darwinian Medicine or vulnerability approach is the most radical version of clinical evolutionary psychology. The approach that considers that disorders or symptoms of disorders are adaptive, examples range from Andrews and Thompson (2009) who consider major depressive disorder and rumination adaptive (but see also Kennair et al. 2017), to researchers who consider psychosis to be adaptive from a group of selectionist perspective (Polimeni and Reiss 2002). It must be said that also within seemingly maladaptive states, such as psychopathology and even suicidal behavior (de Catanzaro 1995), the idea that the trait is adaptive is both original and testable, hallmarks of good scientific theorizing. Despite being skeptical of this approach, it is worth noting that even this panadaptationist approach provides grounds for basic empirical testing, which the field of evolutionary clinical psychology sorely needs.

Problems Within Evolutionary Clinical Psychology

Looking at clinical psychology from an evolutionary perspective is useful for the same reason that it is so useful in psychology generally: It provides a unifying framework for generating hypotheses about human nature. However, there are many unsolved problems within evolutionary clinical psychology.

The Problem of Explaining Diseases as Evolved Traits

Evolutionary psychopathology is a young field and pitfalls and dead-ends are expected (and often useful) in a young science. Nesse (2011) has provided 10 useful questions to ask when doing evolutionary studies of disease vulnerability, the first of which is:

“Is the object of explanation a uniform trait in the species, or is the goal to explain variations in a trait among groups or individuals?” Many adaptive hypotheses of psychopathology typically fail to be clear on that first question, or ignores it altogether.

Questions such as “why did schizophrenia evolve?” can be misleading because it suggests that we need to find hidden evolutionary advantages that the disease may have. A more useful evolutionary question is to ask why humans are vulnerable to developing diseases such as schizophrenia, anxiety, and depression (Nesse 2011). In practice, this entails to have an adaptive approach to species-typical design, for example, for understanding mood systems involved in fear and sadness, in what situations they are activated, and the selection pressures that caused their design, and then disentangle how that design leads humans vulnerable to dysfunctions in those systems.

The Problem of Genetic Variation

Successful genetic variants will spread throughout the population. Therefore, selection reduces genetic variance over time. For this reason, evolutionary psychologists often assume that the heritability of evolved adaptations should be very low. If there is no genetic variation, genes cannot explain differences among people. Evolutionary psychologists are interested in evolved psychological adaptations, and have therefore assumed that genetic variation between people is largely fitness-irrelevant noise or exist entirely for creating biochemical differences that are useful for defending against pathogens (Tooby and Cosmides 1990). However, humans differ dramatically on psychological traits, and it has become increasingly clear that a substantial proportion of this variance is due to genes (Polderman et al. 2015; Turkheimer 2000).

It is an important evolutionary question *why* these genetic differences exist (Zietsch et al. 2015). There are three main evolutionary forces that can account for the maintenance of genetic variation (Arslan and Penke 2015). The first is mutation-selection balancing. Here, the genetic variance is constantly a balance between new

deleterious mutations and their eventual removal by selection. The second is neutral mutation drift, which means that genetic variance is maintained because these variants are neutral to selection, and hence their introduction and removal are due to chance. The third is balancing selection, which is a group of evolutionary processes that actively maintains genetic variance because their relative frequency is adaptive in particular genetic and environmental contexts.

Evolutionary theories of psychopathology, for example of depression (see ► [Depression](#) chapter, this volume), typically only considers neutrality or balancing selection as potential forces that can explain genetic variance underlying psychopathology. In all likelihood, Darwinian psychiatry and psychopathology has concerned itself primarily with balancing selection because it keeps natural selection at the causal forefront. However, to explain heritable genetic variation, other types of evolutionary tools than pure adaptation are required. Explaining genetic variation is simply different than explaining species-typical traits (Keller and Miller 2006).

If mental disorders were maintained by balancing selection (for example, negative frequency-dependent selection), we would expect that just a few genes maintain the prevalence of the disorder in the population. In recent years, though, it has become clear that most human traits, including psychopathology, are extremely polygenic. That is, genetic variation is caused by thousands of genes that individually have very low effect sizes (Chabris et al. 2015). Further, inbreeding increases the risk for serious psychopathology (Rudan et al. 2003). These facts are more consistent with severe psychopathology being caused by the constant influx of new mutations into the human genome (Keller 2008). The brain, after all, is so complex that it has a large “mutational target size,” meaning that most mutations affect the development of the human nervous system. Further, because people of similar genetic quality mate with each other (assortative mating), genetic variance increases and is maintained. Hence, mutation-balancing selection is the most likely candidate for explaining the

maintenance of genetic variation underlying serious psychopathology, not balancing selection.

The Problem of Evolutionary Mismatch

A popular idea within evolutionary approaches is that modern living conditions result in pathological development or do not stimulate mental mechanisms adequately within their expected bandwidth for normal development or output (Kennair 2003) “Diseases of civilization” such as diabetes, obesity, and heart disease increased in western or modern societies after the agricultural and industrial revolution. However, when traits are expressed due to mismatches (depression caused by lack of exercise), that trait is not in itself an adaptation, but rather a manifestation of a vulnerability arising from evolved design. This perspective is often not considered fully in adaptationist hypotheses of mental disorders. It might be worth noting, though, that modernity has been blamed for malaise since the seventeenth century. Some ideas such as breakup of extended family care influencing especially young female depression, or reduced fatty acids in food, reduced physical activity, have all been suggested as explanations for mental disorder. Sandseter and Kennair (2011) suggested that reduced natural risky play among children, and less exposure for emotionally activating setting, might, in general, increase phobias and emotion regulation in the population.

Specific Disorders

There have been formulated a large number of specific evolutionary theories for each of the specific disorders. These have, in general, generated little empirical evidence and had limited influence on mainstream mental health research or care. The exception is evolutionary approaches to fear and phobias. Some approaches are adaptationist, some focus on mismatch, others invoke life history theory, some balancing or frequency-dependent selection, and there are even a few group selectionist approaches. This lack of integration is one of the field’s great limitations. Establishing a few criteria, such as a focus on evolved mental mechanisms and

a Harmful Dysfunction analysis of pathology, might be beneficial for future integration and a more comprehensive research program (Kennair 2011). Most importantly, the field needs to be able to communicate better with mainstream mental health care, and also generate more data to improve the unfortunate theory:data ratio. The following section will address some of the evolutionary theories and speculations for some central-specific mental disorders.

Anxiety

One of the best understood areas of mental disorders is the anxiety disorders. Due to an evolutionary and functional approach being considered fundamental by most anxiety researchers and therapists, we consider normal fear to be adaptive and functional because it elicits species-specific defense responses and potentially lifesaving avoidance (Kennair 2007; Marks and Nesse 1994). Consequently, we understand that contextually exaggerated fear responses, anxiety, will result in nonfunctional safety behaviors and maladaptive avoidance. This lays the ground for treatment in general, as we may learn what is and what is not dangerous, threatening, or painful: systematic exposure and prevention or discontinuation of maladaptive or unhelpful safety behaviors. Some of the safety behaviors consist of cognitive processing, others external behavior. The different anxiety disorders are thus defined by what the patient has exaggerated fear of and what maladaptive safety behaviors maintain this fear.

Along the way, there has been a shift from treating anxiety disorders in general from a behavioral perspective (Marks and Nesse 1994), which mirrors the historical shift in evolutionary research on human behavior, namely from behavioral sociobiology to the cognitive science of evolutionary psychology. Specific disorders are treated with largely specific treatments. While specific phobias are effectively treated with one-session exposure, other anxiety disorders are treated with more cognitive and metacognitive approaches (Kennair 2007). There is probably too little attention on new effective clinical treatments within evolutionary psychopathology.

Generalized Anxiety Disorder

The identifying feature of GAD is worry. Worry is largely based on verbal processing of negative, often catastrophic anticipation of future events. There are therefore few relevant animal models. It is further unclear whether worry at subclinical levels is adaptive; it might be a form of the classical cheater detection mechanism that breaks our confirmation bias and makes us reconsider our risky course of action. Young men seem to have increased mortality compared to middle-aged men and women (Kruger and Nesse 2004), most likely due to hypophobia, while women are more worried and develop generalized anxiety disorder more than men. The evolutionary underpinnings of generalized anxiety disorder need further work based on an integrative evolutionary approach to worry (Kennair et al. in prep).

Obsessive Compulsive Disorder

Obsessive Compulsive Disorder (OCD) is probably one of the more wrongly conceptualized disorders: sometimes compulsions are compared to repetitive behavior and perseveration, which is wrong. It is not as much a neuropsychological condition as a neurotic disorder. Del Giudice's (2014) suggestion that there is an impulsive and dangerous subgroup, is probably not correct (we would treat people with OCD who were afraid of what they might do with knives by exposing them to knives) (Kennair 2014). Boyer and Liénard (2007) precaution system approach is neither fully precise, as their description might be more correct for the danger monitoring and anticipation of generalized anxiety disorder. Finally, the idea that OCD should be a result of brain sequela, due to childhood throat infection, is unlikely. How a few sessions of exposure and response behavior should be able to change neurological dysfunction or sequela is hard to conceptualize. OCD is to a large degree a disorder of neurotically (or magically) attempting to control the uncontrollable – and especially the compulsion is about neutralizing the obsession. From a normal disgust and hygiene perspective, it may come across as hyperactivation of disgust systems, but it is worth noting that it is the anxiety

or disgust the patient is attempting to remove with excessive washing, rather than really attempting to become clean. From a behavioral therapy perspective, compulsions are pretty simple to treat: exposure and prevention of the safety behaviors (Solem et al. 2009). From a metacognitive perspective, it is a disorder of beliefs about effects of thoughts (the power of the obsessions). Obsessive thoughts may be thought to govern the patient's behavior against the patient's own will (thought-action fusion), to change future events (thought-event fusion), or thought-object fusion, where essential qualities of objects may contaminate the patient (like curses or talismans). Alas, there are no current evolutionary perspectives on obsessions from a metacognitive approach.

Panic Disorder and Agoraphobia

Panic, as flight, has been considered the adaptive foundation of panic disorder. It is unlikely, though. While untethered escape expending all resources probably is a good way of escaping some external threats; panic disorder rarely involves escape or caloric expenditure during attacks. Rather the four things people fear is based on misinterpretations of bodily symptoms of activation – in other words a catastrophic misinterpretation of anxiety symptoms: fainting, having a heart attack, choking, and going mad. The safety behavior that patients engage in reflects this. Typically lying down is more typical than running away, in fear of fainting and heart attacks. One of the recurrent problems with evolutionary approaches is that they have not considered the functional psychotherapy interventions that reduce the maladaptive safety behavior that the patient is engaged in and that maintains the anxiety. Especially, there is a lag as cognitive and metacognitive methods have proven to be efficient (Kennair 2007). There probably ought to be more feedback from the functionalist therapeutic methods to evolutionary approaches.

In the case of panic disorder, any misinterpretation of bodily symptoms causing anxiety is possible. There is therefore reason to believe that there are few relevant animal models. The evolutionary roots will probably lie in the mental mechanisms involved in interpreting signals of danger,

but given that cultural explanations are invoked (heart attacks in Western contexts or djinns in Muslim cultural contexts), it is also relevant to consider the cultural transmission of dangers. Among many therapists, there is a fear that the patient may faint; but this is not the case. The important question, therefore, must be: why do we have the capacity to scare ourselves into panic attacks, with unfounded beliefs about imminent and catastrophic danger?

Social Anxiety Disorder

Social anxiety is characterized by an intense fear of possible negative evaluations by others. Hence, the patients with this condition avoid social situations that are perceived as threatening.

It is likely that social mammals like human beings evolve motivations, affects, and behaviors that increase the chances of managing the fitness-relevant resources that groups contain. Social fears can adaptively work as inhibitors of murder, mate-poaching, stealing, and so on (see the ► [Social Anxiety](#) chapter in this volume and Buss 1990). Öhman (1986) has argued that humans fear dominant and aggressive others because it is useful for avoiding tissue damage. Other evolutionary theories of social anxiety propose similar functions, namely to protect oneself from physical aggression and to avoid exclusion from social groups (Trower and Gilbert 1989). Another theory is that social fear exists in order to regulate and enhance self-representation and relational value (Leary et al. 2014).

Social exclusion is very harmful to humans, and adaptations have evolved to make it painful (Baumeister and Leary 1995). Humans avoid it at all costs. However, are the symptoms of social anxiety disorder in themselves evolved adaptations? There is no evidence to suggest that people without social anxiety disorder experience any damage to their physical safety, social status, or reputation. It therefore seems most likely that social anxiety disorder is a dysregulated activation of otherwise adaptive features of the human mind.

Specific Phobias

Beyond the function of fear and general understanding of fight-flight-freeze and species-specific

defense responses, the most obvious contribution of evolutionary perspectives to the anxiety disorders is the understanding of preparedness in phobias (Öhman and Mineka 2001). There are many phenomena in the world that may be dangerous to us, but that we do not fear, despite many health and safety campaigns by the authorities. In many cases, this is due to mismatch. On the other hand, we fear spiders, snakes, heights, the dark, and strangers much more than what is reasonable. Specific phobias are defined as exaggerated fear of these specific phenomena (combined with maladaptive avoidance or safety behaviors). There is continuous evolutionary inspired research on prepared and specific mechanisms involved in phobias based on this tradition (see chapter on ► [Fears and Phobias](#)).

For many decades, we have known that one-session systematic exposure (with response prevention) is an effective treatment. The effective behavioral approach to treatment resulted in a widespread belief that these phobias were conditioned. In recent years, longitudinal studies suggest that phobias appear due to natural maturation (known as nonassociative pathways) and then disappear due to developmental processes (Poulton and Menzies 2002). Sandseter and Kennair (2011) suggested that children's natural tendency to engage in risky play motivates them to naturally expose themselves to situations that previously were dangerous to them, but that they actually can cope with as they develop.

Blood Injection Injury Phobia is a special case. Rather than causing increased activation and escape (fight and flight), this is the only anxiety disorder where the patient actually faints (unlike panic disorder, where the patient fears fainting, but does not). From an evolutionary perspective, this may be adaptive, as increased physical activation and adrenalin might be deleterious and dramatically reduced blood pressure might be beneficial if there is risk of severe blood loss (Kennair 2007).

Depression

It is estimated by World Health Organization that unipolar depression will become the second leading cause for disability in the world by 2020

(WHO 2001). Given the overwhelming social and economic consequences of the condition, an effort to understand why it exists at all should be a major concern for the academic society. Although an evolutionary understanding has shown to be useful for guiding clinicians in the treatment of various anxiety disorders, this is not the case with depression. In fact, with the present state of the field one can get very different recommendation for treatment practice dependent on which evolutionary theory that is endorsed (Kennair et al. 2017). Perhaps because of the lack of consensus in evolutionary understanding, mainstream research on clinical depression is seldom guided by predictions drawn from evolutionary theories of depression. Clinical practice is even less so.

An evolutionary analysis will have to address the fact that depression is common, but at the same time having obvious fitness reducing consequences, like reduced interest in reproduction. How is it that a phenomenon evolves to be both debilitating and common? Most clinician's unfamiliar to evolutionary thinking assume that depression is a harmful dysfunction, meaning that they think of depression as a malfunction of the emotional system. Contemporary clinicians thus look for environmental, developmental, or neurobiological abnormalities that could explain the syndrome (Beck and Alford 2009). Nettle (2004) has made the argument that depression is a harmful dysfunction based on an evolutionary analysis. However, an evolutionary approach also must consider that depression can be an adaptive response to fitness relevant triggers that is part of the common architecture of the human mind.

There are two broad categories of adaptive evolutionary theories of depression; the involuntary behavior inhibition category and the social bargaining or social problem-solving category. In the involuntary behavior inhibition theories, depression is viewed as beneficial because it retracts the individual from investing or taking risk when there exists information that such behavior is unlikely to be rewarded with fitness relevant gains (e.g. Price et al. 1994). So the function is to downregulate the normal workings of other psychological mechanisms. Depression is thus a "negative" adaptation, in the sense that it

downregulates other adaptations in contexts where those other adaptations are detrimental to fitness.

Both the bargaining theory and the social problem-solving theory view depression as a "positive" adaptation, in the sense that the syndrome of depression solves unique adaptive problems that the psychological architecture of the human mind would not otherwise be designed to solve. In bargaining theory, depression is viewed as honest signals about the inability of the individual to contribute to a shared fitness relevant investment. This would again force the significant others to invest more or lose all. Hagen (1999) uses the case of post-partum depression as an example of such. If the mother (or father) receives information that their partner is contributing less than necessary, this could trigger a depressive episode that would force the partner to contribute more or lose the baby. Andrews and Thomson (2009) suggest that depression is designed to enhance social problem-solving. They postulate that the symptoms associated with major depression help individuals think repetitively about what caused, and how to deal with, complex social problems. They assume that repetitive analysis will lead the depressed patient to solutions that ultimately solve the problem of navigating the social environment.

The clinical consequences of these evolutionary approaches to depression are very different. Proponents from the involuntary behavior branch typically view major depression as being a result of excessive downregulating of normal psychological mechanisms, meaning that the adaptive function of normal depression is lost when depression has become severe. However, proponents from those who endorse the view that depression is a "positive" adaptation typically do not view major depression as dysfunctional. In the social problem-solving approach, the severity of depression is thought to vary with the complexity of the social problem. Clinicians informed by this theory would help their patients increase their rumination to solve the underlying social problem. Clinicians informed by an involuntary behavior inhibition approach would assume that a patient with major depression need techniques that either helps them

upregulate the workings of the psychological mechanisms downregulated by the depression, or techniques that alleviate the downregulation from the depression.

Bipolar Disorder

Bipolar disorder is estimated to affect at least 1% of the population worldwide (Alonso et al. 2011). When considering subthreshold bipolar disorder and cyclothymic disorder, the combined prevalence rises to 2–4% making the suffering associated with the bipolar spectrum significantly detrimental to mental health (Grande et al. 2016).

Compared to unipolar depression, there are few adaptationist theories about why bipolar spectrum disorders exist. There are two main views in the literature on the evolutionary origin of bipolar disorder. One line of argument focuses on the assumption that constituent traits associated with bipolar disorder are adaptations, but that the disorder itself is not. Those constituent traits are thought to increase the mate value of the individual through increased performance in artistic activities, better leadership, or social skills, depending on the affective temperament in question (Akiskal and Akiskal 2005). Although experiencing maladaptive consequences, such as psychotic episodes during mania, individuals with bipolar disorder might benefit from those characteristics. In addition, even if the disorder is causing severe maladaptation in some individuals, the “good genes” might get a more benign expression in the phenotype of the children of the sufferers. This would mean that there is a balancing selection between lack of reproductive success in one generation versus success in the next.

The other main view about the evolutionary origin of bipolar disorder argues that the syndrome of bipolar disease, as a whole, is an adaptation, including the manic episodes in bipolar I. In the perhaps most provocative version of that proposition, Sherman (2012) theorizes that the phenotype that is seen in the circular (alternating between manic and depressive episodes) version of bipolar I is an adaptation to severe northern climate during the Pleistocene. This is a hybridization of theories derived from earlier findings about the association between the bipolar

spectrum and (1) biological clocks and seasonal alternations in mood, and (2) pyknic (compact, cold adapted) physical characteristics. Bipolar disorder is thought of as a human equivalent of hibernation and involves an optimization of resource allocation during winter and summer where risky behaviors are postponed, through depression, to the more agreeable season. However, if the conditions become bad enough so that a risk averse strategy would not work (i.e., the food storage runs out), the gambling strategy would be the only way out of certain death. Sherman (2012) thus proposes that the capacity for mania could be an adaption to the problem of emergency. She argues that the syndrome first evolved among the Neanderthals because they experienced extreme selection pressure toward solving the adaptive problem of cold climate without advanced technology such as clothing and shelter construction. The genes associated with cold resistance eventually ventured to the human genome through interbreeding between Neanderthals and those of the *Homo sapiens* that left Africa before the Neanderthals went extinct.

New research has concluded that part of the human genome derives from Neanderthals (Green et al. 2010). Even so, the hypothesis that bipolar disorder derives from this population remains controversial. It would mean that those who are decedents from ancestors that never left Africa would not have the capacity for developing bipolar disorder, at least not the manic episode (Sherman 2012).

Eating Disorders

There are several disorders related to eating behavior such as binge eating, obesity, anorexia, and bulimia. While obesity is a multifaceted issue with many proximate causes, humans possess some key universal adaptive mechanisms that are instrumental for an evolutionary understanding of this disease: First, humans find high calorie and sugary foods delicious, and will often crave such foods. Second, any excess calories they consume will be stored in their bodies as fat and glycogen. These energy reserves were likely critical for survival in an EEA where food was scarce. These adaptations are as powerful

today as they have ever been, even for those of us who now live in an environment with endless access to calorically dense food, and almost no need for exhaustive activity. This is because this type of environment has probably been almost nonexistent in our evolutionary history; hence, there has not been a significant selection pressure against eating too much, or storing too much fat in our energy reserves. An understanding of this mismatch between the EEA and the post-industrialization environment is crucial for understanding obesity and other lifestyle diseases.

Another major eating disorder is Anorexia. Anorexia is a disorder where patients (mostly adolescent girls) are obsessed with weight, and will starve themselves to get rid of imagined excess fat. Life history theory has been a useful analytical framework for understanding this disorder, with key findings suggesting that anorexia is associated with a fast life history. There is a mismatch between adaptive female intrasexual competition and the modern world where there is an intense focus on the attractiveness of thin female bodies, results in disordered eating patterns. These ideas are in opposition to early psychoanalytical theories of anorexia, which propose that sexually repressed girls seek to delay adulthood by starving their bodies. Some evolutionary theorists have also speculated in the adaptive function of delaying reproduction, although anorexia may be a maladaptive approach to doing this.

Personality Disorders

Personality disorders involve enduring problems in interpersonal functioning due to maladaptive and inflexible behavior, cognition, and emotions. However, this general mental health definition to personality disorders does not consider that sometimes personal feelings or social desirability of a phenomenon says nothing of whether an evolved mechanism is working or not. Further, while personality disorders are generally conceptualized as disrupted development or extremes of normal personality, an evolutionary approach might consider how different personality disorders may be expressions of normal variation or different evolved morphs.

An example of this is the evolutionary analyses of psychopathy in which we both find mental mechanism failure approaches (true Harmful Dysfunction psychopathology), normal variation in black triad traits, and the suggestion that there are two types of psychopathy: the frequency selected approach to exploiting others and a developmental ecologically elicited adaptive response to circumstances (Mealey 1995). Especially, the frequency-selected approach is of interest. If everyone was antisocial and exploitive, there would be no socially generated surplus to exploit, but if the majority is prosocial and cooperative there will be a possible surplus for to parasitize. Lack of empathy might therefore be beneficial to many in some situations or to a small minority across social contexts. In that case, despite diagnosing lack of empathy, this might not be due to mental mechanism dysfunction – the lack of empathy might be a sign of evolved function.

Borderline personality disorder is another disorder that has received attention from an evolutionary perspective. Typically, patients with this disorder have unstable relationships, unstable mood, and a sense of chronic emptiness. Brüne and colleagues focus on how facets of borderline personality disorder including unstable relationships, impulsivity, and sexual risk behavior may be understood from an evolutionary life history perspective (see also Del Giudice et al. 2014). As such, some of the traits of borderline personality disorder may be considered extreme versions of adaptive traits in contexts of low long-term investment. It is worth noting that this research is in line with other correlational research where shared parent-offspring genetics might both predict unstable childhood experiences and impulsivity and unstable relationships as an adult. In general, all such research needs to control for genetic influences. Also, other personality disorders may be due to extremes or maladaptive combinations of adaptive traits. Nettle and Clegg have shown how facets of personality disorders may be beneficial to mating success, as in the case of schizotypy. While the personality disorder in itself may be problematic, some of the symptoms may be linked to fitness enhancing traits.

Schizophrenia

The prevalence of schizophrenia is roughly 1% across all human cultures. This universality suggests that schizophrenia has been a part of the human condition at least since humans first migrated from Africa. In addition, findings from twin and adoption studies show that schizophrenia is highly heritable. If we also consider the fact that schizophrenia is a dramatically debilitating disorder, an important question emerges: Why are the genes responsible still in our gene-pool? This has been called the schizophrenia paradox, and has attracted much attention from evolutionary psychopathologists. Evolutionary models of schizophrenia include group selectionist explanations, viral explanations, explanations from social hierarchy theory, as well as nutritional explanations – proposing increased prevalence of schizophrenia due to decreased intake of fatty acids. However, Crespi and colleagues have found that genes associated with schizophrenia show signs of selection. While their results does not indicate why these genes are selected, they do support a by-product theory of schizophrenia fronted by Timothy Crow: This model proposes that the genetic evolution underlying our language capabilities and hemispheric lateralization, the very mutations that made us human, also made us vulnerable to schizophrenia (Crow 1995).

It has also been suggested that schizophrenia is at the extreme unattractive end of human fitness indicators (Shaner et al. 2004, 2008). Fitness indicators such as language and other courtship abilities evolve to attract mates and are associated with reproductive success. All evolved fitness indicators (“good genes” indicators) will have an unattractive low-end to them, hence it is possible that the heterogeneous schizophrenia symptoms are simply manifestation of failed sexually selected fitness indicators, not adaptations in themselves.

Sexual Dysfunctions

Sexual dysfunctions in men need to be explained from an evolutionary perspective, although a large number of these may be explained by current medical conditions or other mental health disorders (Apostolou 2015). There would have been

very strong selection against any condition that reduced reproductive ability. In explaining why three different male sex dysfunctions – premature ejaculation, erectile dysfunction, and male hypoactive sexual desire disorder – exist today, Apostolou bases his analyses to a large degree on very limited female choice in the EEA and the resulting mismatch or ancestral neutrality. There was therefore, according to Apostolou, no need to extend sexual intercourse beyond 1 min, no reason to have performance anxiety (a major factor in erectile dysfunction in younger males), or need for long-term oriented males to mate continuously. There is therefore no true dysfunction involved, rather a new context with greater female choice that changes the evaluation of harmfulness (or undesirability) of the behavior – but from a Harmful Dysfunction analysis sexual dysfunctions are not considered psychopathology by Apostolou.

The same is the case for female sexual dysfunction. Considering the typical female sexual dysfunction of low sexual desire, Apostolou (2016) suggests that in the ancestral context there was balancing selection of morphs with low and high sexual desire where both are favored. In addition, though, there were less negative consequences of low sexual interest due to less conflict with parents about premarital sex, and less choice in relation to partners about when to have sex. This is thus partly a mismatch approach, suggesting that what may be deemed dysfunctional in modern society was not fitness reducing in the EEA. This is, as in the case of male sexual dysfunction, based on the premise that there was little or no female choice. These first analyses of sexual dysfunctions are based on specific premises that may be considered controversial. The predictions need to be tested empirically.

Recently in an investigation of sex differences in type and degree of Negative Postcoital Emotions, the different feelings associated with the wish to detach in males and bond in women after short-term sex, show signs of adaptation (Fernandes et al. 2016). This despite most mental health research into the topic has suggested that this may be pathology.

Substance Abuse and Dependency

Substance abuse and dependency is a very costly set of mental disorders, both in terms of economic concerns and human well-being. There is no brief way to account for the etiology of these disorders, and any satisfactory explanation would need to address many proximate factors from several fields, such as biochemistry, genetics, history, social science, etc. Notable among recent contributors from an evolutionary perspective is Hagen et al., who proposes that the EEA was substance rich, and that substance seeking may protect against parasites, which may suggest adaptive reasons for recreational drug use. This is contrary to the “conventional” evolutionary perspective, which assumes a substance-free EEA, and substance abuse being a result of a mismatch after the introduction of substances of abuse into our environment. Other evolutionary approaches, such as life history theory, have also been fruitful, bringing with it biopsychosocial integration, and testable hypotheses and original ideas.

Evolutionary Informed Psychological Treatments

To date, there are few therapies that are more than merely metaphorically informed of evolutionary theory; despite both Freudian psychoanalysis being influenced by phylogenetic musings and Bowlby's attachment theory being specifically based on evolutionary understanding. Further, even fewer of these have been empirically tested. On the other hand, most who treat anxiety will consider the functional aspects of safety behaviors and specific albeit exaggerated fear, and will accept at least functional but most often explicit evolutionary underpinnings. In addition, they will probably involve at least some functional/evolutionary reasoning in psychoeducational interventions to explain both the normalcy of fear and the function and psychophysiology of anxiety.

Among actual evolutionary based interventions, there have been some attempts at targeting supposed environmental mismatch with the EEA that might cause depressive symptoms and also adding an adaptiveness approach to CFT. The problem is

peer reviewed clinical trials. A treatment that has at least one randomized controlled trial with a clinical sample is Gilbert's Compassion Focused Therapy. Obviously, there is a need for more studies, although few evolutionary psychopathologists seem to have aspirations beyond providing psychoeducation based on insights from evolutionary theory and knowledge about the EEA.

Conclusion

Ever since Freud, evolutionary perspective has informed discussions of both normal human nature and psychopathology. For most of these years, evolutionary approaches to mental disorder have mainly been a theoretical enterprise. Despite many different theories and book length expositions of the field of mental health care from various evolutionary perspectives, few of these efforts resulted in any empirical testing. This may be changing. The controversy surrounding the adaptive nature of rumination, for example, has resulted in different groups considering the benefits of specific types of rumination, and this is expected to result in future development and data collection. Further, Del Giudice's taxonomy of mental disorders based on Life History Theory also opens for empirical testing. There is reason to believe that in the near future, the theory to data ratio, that has been troubling high for development and relevance of the field will improve, and data-driven discussions will develop our knowledge of how symptoms may or may not be adaptive and why some evolved vulnerabilities result in harmful dysfunctions.

Definition

The study of the psychological mechanisms, naturally selected throughout human evolutionary history, underlying violence, and crime.

Introduction

Criminology, since the nineteenth century, has proposed to examine the transgression of formal law, chasing scientific explanations for a vast plethora of human behavior that could be classified as crimes. As an interdisciplinary field, it tries to articulate different sources of knowledge, e.g., psychology, sociology, biology, or political science, rather than restraining itself in only one aspect when evaluating criminal matter (Durrant and Ward 2012). Despite acknowledging this potential contribution of many disciplines for the understanding of crime, many criminologists point out that, in reality, the field has been dominated, in most part, by the sociological perspective (Barnes et al. 2015).

Although criminology has actually begun with biologically oriented studies, before the emergence of the sociological perspective (see Lombroso 2006), in recent years, research concerning organic and biological aspects has gained importance. Due to this, once *nothing in biology makes sense except in the light of evolution* (Dobzhansky 1964), the variables that are taken into consideration when studying crime and similar topics should not be examined without

the proper comprehension of the evolutionary context that leads to the endurance of some anti-social behaviors.

Basic Principles

Evolutionary psychologists have been analyzing different aspects of human evolutionary history that could have been responsible for the emergency of violent and antisocial behaviors, its selection throughout history, and its maintenance in present days (Barnes et al. 2015). In other words, the main proposition of evolutionary criminology is that the kind of behavior that modern societies classify as crimes was naturally selected over a millions of years' period. Nonetheless, these researchers recognize that not all acts of violence are driven by specific selected mechanisms. Otherwise, some are by-products of those (for more details, see Goetz 2010).

Violence appears as natural mechanism that evolved along with other prosocial behavior and is intrinsic to humans and other species. Despite those acts being harmful to the group as a whole, evolution can mold conducts that are not considered to be ethical or moral, once these can be successful to the individual in a given context. This means that they serve the purpose of solving an adaptive problem, like increasing fitness or facilitating reproduction. This aspect brings up an important characteristic about interpersonal violence among humans: it is not random. Rather, it is context-sensitive evolutionary trait that serves specific purposes that favor survival and/or mating success (Goetz 2010). They rely on specific contexts with stimuli that could indicate a high probability of reward. For example, the necessity of feeding will only be safely satisfied if the individual, in the presence of a predator, could restrain itself. In another delicate circumstance, a mate pursuit, for instance, depends on the absence of a dominant male and the presence of sexually available females. The capacity of self-control in these scenarios represents an evolutionary adaptive mechanism, preventing lethal conflicts (Durrant and Ward 2012). Therefore, it is logical that

classical criminological theories, e.g., general theory of crime (Gottfredson and Hirschi 1990), use the self-control as a central mechanism to understand criminal conduct.

These comprehensions help to address old issues on the criminological field. Yet, evolutionary criminology does not sign this kind of behavior as inevitable or mechanically determined, but rather, they study the environmental triggers that promote these types of responses, in order to reduce their occurrence.

Classic Criminology Issues and Evolutionary Propositions

One of the most recurrent problems that emerge from classic criminological research is the gender gap in crime rates, by which men are consistently more involved in criminal activities than women. For this matter, evolutionary psychologists comprehend this disparity in the context of mating competition and parental investment (Buss 2015). To achieve reproductive success, both men and women often have to compete with same-sex individuals to be able to pass along their genes to the offspring and guarantee its survival. Nonetheless, those substantial differences on the parental investment provided by males and females to offspring survival are what could explain this gap. Since human males present less parental investment, they are unable to face more severe selective pressures. Once they do not have to concern as much with the offspring as female, considering they don't go through gestation and nursing, they are more inclined to adopt risky behavior, such as violence. Moreover, in human history, females, more commonly, had the power to choose their partners. Thus, men usually had to compete with each other to be able to mate. This dispute, more often than not, involved displays of might through aggressive behavior (e.g., gang fight) or, less frequently, violence encounters that eventually led to injury or death. This is the handicap principle, which approaches the perspective that when the male succeeds after facing a great risk, such as a struggle, he can prove his quality as a strong and powerful mate to the female (Zahavi 1975). Women, otherwise,

have an extensive expense during the process of choosing partners, mating, gestating, and nursing the offspring. Consequently, as a trade-off, once women do not have the selective pressure to prove her quality by engaging herself in such violent behaviors, the energy can be allocated to ensure the survival of both herself and the offspring.

Other issues that are rarely addressed by classical criminologist and are given plausible explanations by evolutionary criminologists are the crimes of infanticide and parricide. In a few mammals, the majority of offspring of a certain group would come, mostly, from when a dominant male mates with several females of the group, achieving a monopoly of the reproductive chances. Due to this, for a given period of time, these females would not be reproductively available, given the period of nursing of the children (Lukas and Huchard 2014). So, to achieve the possibility to reintroduce the women in the reproductive process by shortening the postpartum infertility, males would kill the offspring of rival males, eliminating the genes of their rivals in future generation and also being capable of mating with the females again. In other contexts, mainly in resource-scarce environments, parents would kill their own children. In these cases, individuals would not be driven by mate competition, but rather by the need to ensure one's own survival (Liddle et al. 2012; Lukas and Huchard 2014).

As for parricide, it can be defined as the act of killing a parent, a crime in modern society. Despite being considered a criminal behavior, from an evolutionary perspective, the killing of a parent does not genetically represent any disadvantage to the gene perpetuation. That's because gene natural selection occurs by genetic heritage, so the real value of the species perpetuation is contained in the offspring (Ridley 2009). Nevertheless, this behavior could be interpreted as a status manifesto, a dominance achievement on the group hierarchy, and a conflict of interests. This is due to the value of an individual in a group, once children are extremely valuable for their parents, because they represent a vehicle of their parents' genes. Yet, they are only 50% genetically related. Therefore, in human evolutionary history, an individual loses his value to their children as

they grow old, facing a great risk of being killed by their own offspring, once they become less valuable with time (Buss 2015). For that reason, young individuals, who have not yet achieved mating success, are even more inclined to displays of power that can escalate to violent behavior (Liddle et al. 2012).

Conclusion

Evolutionary criminology recognizes that, like in many other species, violence is a natural behavior which occurred persistently in given contexts throughout the evolutionary human history. The contextual aspect of this conduct leads to the fact that humans, despite using violence as a form of achieving higher statuses, gaining or maintaining resource, or having mating success, are not necessarily violent by nature. Otherwise, violence and psychological mechanisms underlying it have emerged as a viable way of the enduring evolutionary pressures. Negating the influence of naturally selected psychological mechanisms on the emission of acts that lead to crimes diminishes the possibility of the comprehension of modern antisocial behaviors, as well as complicates the prevention of such acts. Once these are not mechanically determined, the understanding of this mechanisms and the triggers that activate them could possibly contribute to reduction of their frequency, avoiding the contexts that produce them.

Definition

Cultural evolutionary psychology is an approach to study the evolution of culture applying the evolutionary psychology perspective based on the concepts and knowledge of Darwinian evolutionary process.

Introduction

Culture: Definition and Concepts

Humans depend on cultural learning for all aspects of lives like managing resources, protecting family, wooing a mate, enhancing status, or forming political alliances. This shows that humans are cultural species. Our cultural experiences shape our ideas, values, feelings, and strategies. Psychological processes in humans like self-concept, social orientation, cognitive reasoning, aggression, and moral reasoning have been found to be influenced by cultural variations (Nisbett et al. 2001; Heine and Buchtel 2009). Various definitions of culture have been given. Richerson and Boyd (2005) have defined culture as “information capable of affecting individuals’ phenotypes, which they acquire from other conspecifics by teaching or imitation.” Another definition given by Laland and Hoppitt (2003) says culture is a “group-typical behavior patterns shared by members of a community that rely on socially learned and transmitted information.” These definitions show that social learning is majorly the way in which information is acquired from one member of one species to another member. Cultural learning is not just confined to humans. Many other species like pigeons (Lefebvre and Giraldeau 1994) and rats (Galef 1988) also engage in cultural learning. In chimpanzees cultural learning is quite substantial (Whiten et al. 1999). Though cultural learning is not just restricted to humans, the learning from conspecific in humans is unique (Herrmann et al. 2007). It is unique in humans in two ways: firstly they have linguistic abilities which allow better communication, and secondly they have a well-developed theory of mind which helps them to understand the intentions of the fellow humans. Thus humans are able to do imitative learning in the true sense as they are better able to understand the intentions of their comrades. Some other species like chimpanzees also engage in social learning, but it is not fully imitative because they are not able to understand the intentions of their conspecifics.

Cultural Evolution

Concept and Relevance

Cultural evolution uses the Darwinian evolutionary process to understand the cultural change in humans and other species with the help of concepts, tools, and methods used by biologists to study biological evolution (Mesoudi 2011). Cultural evolution researchers try to explain the complexity of culture and changes in cultural phenomena just like how the evolutionary biologists try to explain the diversity of life and living organisms. In recent times the cultural evolution research has been on the rise. Works of evolution are seen even before Darwin published *The Origin of Species* in the historical descent of languages. The descent of language is based on the similar principle of Darwin in the sense that there are no genes for languages like English or Hindi and it is transmitted socially (van Wyhe 2005). It evolves over time, and language once extinct never reappears. Certain new words come over time, and preservation of certain words is based on natural selection.

The theory of evolution as given by Darwin is based on three principles (Lewontin 1970):

- (i) Principle of variation – which says that entities differ in their characteristics.
- (ii) Principle of differential fitness – which says that entities have different rate of survival and reproduction.
- (iii) Principle of inheritance – there is a correlation between parent and offspring entities in those characteristics that contribute to differential fitness.

Similarly the theory of cultural evolution is based on the theory of evolution in the sense that there is variation in cultural traits (words, ideas, etc.), the rate of survival is different for different traits, and social learning in the form of imitation is the method for transmission of traits from person to person.

Lieberman et al. (2007) have used vast database of English verb usage over time to quantify

this principle. He found that over 1200 years the usage of verb has evolved over time. They varied in past tense form (principle of variation), and those verbs that were not used much got replaced with the words that were regularly used (principle of differential fitness). It was also found that the verbs were transmitted in different generations through social learning (principle of inheritance).

It is also believed that cultural evolution is not completely identical to genetic evolution. Both are different in certain aspects as well. For example, cultural evolution does not require any unit which is required for genetic evolution. Cultural evolution is also guided by intention of humans; it is not completely blind which is the case in genetic evolution (Mesoudi 2011). Another difference is that cultural evolution can happen even when traits are transmitted from genetically unrelated human beings, while genetic evolution believes that half the genes are transmitted from the biological parents.

Culture Variation

People in different cultures tend to vary in their belief systems, behavior, and practices. Culture variation exists almost everywhere. From food sharing and child-rearing activities to religious belief systems, body decoration variations exist. A thorough understanding of culture variation may explain variation between and within cultures.

Growing cross-culture researches have potential to expand the horizons of cultural diversity, resulting in theories of human behavior gaining greater credibility and generality. Evolutionary psychologists postulate that living beings adapt behavior in response to their environmental conditions. However, adaptive adjustments cannot take place by a single evolved process; rather it requires organisms to behave in a certain way to be responsive to the environment. In short, it means that the possibility of specialized, problem-specific adaptations within group or between groups is what is termed as “culture.”

Another view states that social learning biases and transmission pathways explain how cultural variation is transmitted from one generation to another. The question arises from where cultural variation has originated. Historical evidences suggest that these psychological differences such as individualism–collectivism and analytic–holistic cognition have their origins in the ancient philosophical modes of thought of ancient China and ancient Greece (Nisbett et al. 2001). Assuming that these traits are not genetic forms the basis of long-term cultural macroevolution, just like long-term use of language or tools.

Several hypotheses have tried to explain the origins of psychological differences. One by Chang et al. (2011) has been truly inspired by cultural evolutionary theory. He explained that East–West differences in psychological dimensions as in collectivism–individualism and interdependence–independence are a result of different weightings given by society to social and individual learning. Theoretical models have stated that both social and individual learning are effective means of adaptation and thus there should be a mixture of both (Boyd and Richerson 1995). However, this blend depends on various factors, one of them being environmental change. Stable environment favors social learning, as other knowledge may remain relevant overtime, while unstable environment favors individual learning as other knowledge may become irrelevant with time (Aoki and Feldman 2014).

These insights of Eastern and Western psychological differences were used by Chang et al. (2011). They said the primary means of cultural adaptation in the East (mainly China) was influenced by social learning. It comprises strong social ties and social interdependence, respect for elders and conformity of social norm, less innovation and more rote learning, etc. The primary means of cultural adaptation in the West (Western Europe) was individual learning. It has weaker social ties, less rigid rules for following elders, or existing norms; more focus on science and technology; there is encouragement for creativity and independent thinking; etc. They also postulated that these differences in learning patterns are

related to environmental differences, as there is greater instability and fluctuations in Western Europe than in China in terms of migration, climate, agriculture, governance, etc.

Pathways of Culture Variation

Culture as mentioned is studied as amalgamation of belief systems, practices, values, and attitudes that characterize a group of people. There are basically two naturalistic pathways by which culture variation emerges: evocation and transmission (Tooby and Cosmides 1992).

Evoked Culture

Culture that is evoked from environmental triggers, e.g., war, drought, abundance, etc., is termed as evoked culture. Such conditions “evoke” different behavioral forms resulting in different culture formation. Tooby and Cosmides explain how the same activity like that of food sharing can have different cultural norms. Egalitarian norm of food sharing suggests hoardings are strong where there is variability in success of hunting across time in comparison to where the supply of food is stable. They even put evoked culture at the center of evolution framework.

Food Sharing and Food Variance

Different classes of food have variation in their distribution. Foods of high variance differ greatly in their availability. For example, in Ache tribe of Paraguay, getting meat from hunting is a high-variance resource; it means that some hunters will be successful in a day, whereas others will come back empty handed. Here, food sharing plays an important part, and the benefits of cooperative food sharing increase in such conditions. However, gathered food on the other hand is a lower-variance food resource. Here, surplus from food gathered is dependent more on skill and effort.

Cashden (1980), in the Kalahari Desert, found that San groups are more egalitarian than others. This egalitarianism is highly correlated with the

variance in food supply. In !Kung San's, food supply is highly variable, and having an egalitarian belief system, they therefore share food. Being called a “stinge” (stingy) is one of the worst insults in the group. The group levies strong social sanctions for stinginess and high regard for food sharing. On the other hand, in Gana San food variance is low, and it has great economic inequality. Therefore, they hoard their food and hardly share food outside their extended families.

Therefore, it could be said that environmental conditions can evoke some behaviors, such as sharing and cooperation. Everyone does have the capacity of sharing and cooperation, but environmental differences play a part in the extent of sharing and cooperation in different cultures.

Pathogen Load and Attractiveness

Pathogens always pose threats to the health of any long-lived organism. The host therefore should evolve defenses against these pathogens. However, any solution to the threat of pathogens is never final because pathogens again evolve to overcome these defenses. Pathogens are major killers of humans, especially in the early life period. Therefore, nearly 30–50% of the population in the ancestral human group used to die because of diseases, even before reaching reproductive age (Hill and Hurtado 1996).

Finding healthy mates was thus considered crucial in the human hunter–gatherer groups. Healthy mates are considered to survive for mating and less likely to pass pathogens to the chosen mate and result in more disease-resistant offspring (Hamilton and Zuk 1982).

Overt unhealthy signs, e.g., oozing pustules, open sores, and lesions, are generally disfavored by both sexes. There are also subtle healthy signs. Symons (1979) postulated that “physical attractiveness” function as “health certificates.” Gangestad and Buss (1993) explained that mate preferences shift when a person has high level of parasites. In such situations, physical attractiveness becomes a certificate of current health or an indicator of pathogen-resistant genes. Parasite prevalence is indeed positively correlated with mate preference for both sexes (Buss 1989). These differences were reflecting in evoked

culture as these patterns were due to evolved responses, in mating psychology. The ecological factors were responsible for association between characteristics and mate value (Gangestad and Buss 1993).

Transmitted or Epidemiological Culture

Cultural transmission as the term suggests is the transferring process of cultural information from one generation to another, or from one group to the next. Cultural transmission is a universal process. Cultural evolution takes place through the process of passing off traits (Mesoudi 2011). There are vast differences among cultural traits like belief systems, moral values, and attitudes across the globe. Some of these traits persevere (e.g., some belief systems continue to be relevant over the years and these traits are passed to other persons through social learning). It can be in the form of teaching, imitation, language, etc. (Tomasello et al. 1993).

Cultural macroevolution takes place over large scale and over long period of time and also over large geographical areas. Phylogenetic methods, which use the current distribution of species to study the evolutionary history of those species, are used by biologists to study biological macroevolution. This information helps generate lineage of similar kind of species. Cultural evolution researchers have used the same techniques to construct history of cultural traits by high fidelity cultural transmission, e.g., languages (Bouckaert et al. 2012), folklore (Tehrani 2013), prehistoric tools (O'Brien et al. 2014), and sociopolitical systems (Currie et al. 2010).

However, the process of passing of traits is different from that of genetic mutation. Cultural evolution researchers have studied experimentally on how cultural evolution functions among individuals, genesis of cultural variation, changes over time, and its transmission from person to person. These form the basis of cultural “microevolution” (Mesoudi 2011, 2016; Richerson and Boyd 2005; Richerson and Christiansen 2013). The term “cultural” may be applied to those traits that are transmitted by any process of non-genetic

transmission. Researchers have studied when and why people copy their parents as compared to non-parents. However, learning takes place from non-parents as well, and that is termed as “social learning strategies” or “biases” (Laland 2004). It explains the process of learning. It includes:

1. Conformity – it is described as disproportionately copying the most common trait from the group (Morgan and Laland 2012).
2. Prestige bias – copying from preferentially high-status individuals (Cheng et al. 2013; Henrich and Gil-White 2001).
3. Content biases – it is where specific ideas are preferably transmitted, mainly those that raise social interaction (Mesoudi et al. 2006; Stubbersfield et al. 2014) or disgust (Eriksson and Coultas 2014).

Cultural Transmission Pathways

Cultural psychologists have studied variations among societies in their psychological process. But this variation is maintained over time even with migration happening. What maintains this variation? This can be understood in terms of transmission pathways.

Cultural evolution researches (Cavalli Sforza et al. 1982; McElreath and Strimling 2008) have proposed three channels or directions of cultural transmission in terms of:

1. Vertical cultural transmission – it is learning from one biological parent to the offspring. It includes transmission of personality traits, cognitive development, occupational status, education level, conception of sex role, attitudes toward feminism, sexual activity, political beliefs, religious beliefs, phobias, self-esteem, language, and linguistic usage.
2. Oblique cultural transmission – it is learning from unrelated elders, e.g., teachers/mentors.
3. Horizontal cultural transmission – it is learning from the same generation like peers.

Both oblique and horizontal transmitted traits comprise of aspirations, career and social

mobility, adolescent behavior, aggressive behavior, altruistic behavior, social values, moral values, language and dialect, clothing innovation, conformity, language and dialect, games, and rituals.

It can be noted that some traits are transmitted either way, while others follow a dual inheritance model, and also that vertical transmission is slower change than oblique transmission, which is slower than horizontal transmission. Studies by Hewlett and Cavalli-Sforza (1986) state that parents are majorly a source of knowledge during early childhood, while transmission from knowledgeable elders and peers is more important mainly during late childhood, adolescence, and early adulthood.

Mechanism of Transmission

The process of transmission is a two-stage process. The first stage is of awareness of the information that is to be transmitted, while the next stage is of acceptance of the information. These two stages can be only distinguished when there is a choice to accept or reject and is based on the drive to teach or impart knowledge. Externalization attempts on transmitter side and internalization attempt on receiver side form the basis of transmission process which is influenced by teaching and learning (Kuczynski et al. 1997).

Human beings use their cognitive abilities for acquiring knowledge without any reinforcements, and it is also not restricted to specific learning domain which is not the case with other species. Flexibility and spontaneity are other characteristics present in humans in terms of transmission.

Another view is that all the transmission requires presence of specialized inference mechanisms in the receiver's mind to recreate representations. This mechanism is important because information originating from any individual in a social group is limitless; infinite range of ideas compete for the attention of humans. Evolved psychological mechanism thus must be present in the receiver's mind to gauge the barrage of ideas, selecting only a subset for reconstruction.

Therefore, for transmission of culture, evolved psychological mechanism is required. The mechanism must have the properties such as *selective attention* for attending to some ideas and ignoring others; *selective encoding* for encoding ideas in memory and forgetting others; and *selective transmission* for transmitting some ideas to others while failing to transmit to others. This could best be understood from the example of human's tendency to imitate the clothing styles of high-standard members of their society. The evolved psychological mechanisms caused people to attend to high-status people more than low-status people, encode their clothing style in memory, and access the memory while shopping for clothes (Buss 2007).

Memes

With reference to culture, memes are ideas, behaviors, and even styles that are spread from one person to another within a culture. Its main objective is to convey a particular phenomenon represented in a meme. It acts as a unit of carrying cultural ideas, practices, etc. that are transmitted from one mind to another in the form of writing, gestures, speech, and rituals with a mimicked theme (Gordon 2002).

The traditional view has tried to explain evolution of psychological mechanisms through social learning, but evolutionary psychologists are of a different view saying that learning is not an explanation to psychology but rather it is also a phenomenon like other mechanisms.

Evolutionary Psychology

Emerging Discipline

Evolutionary psychology tries to understand the human mind and how it is designed. The theories and principles of evolutionary biology are applied in evolutionary psychology to better understand the structure of human mind. The approaches by evolutionary psychology are changing the traditional viewpoints in the way that it believes mind to be an information processing machine which was designed to

solve problems arising over time by natural selection.

Charles Darwin in his seminal work on evolution theory had predicted a new foundation for psychology to understand the human mind in the evolutionary perspective. Later on William James in his works on experimental psychology described “instincts” referring it to be specialized neural circuits common to every member of a species and scribed it to be product of that species’ evolutionary history. Collection of circuits of instincts is collectively referred to as “human nature.” Earlier conventional thinking thought that other animals are ruled by instinct, whereas humans have gradually lost their instincts and are ruled by “reason” and that’s why humans are considered much more flexibly intelligent than other animals. William James proposed the opposite view and argued that humans have more instinct than animals, but we tend to be blind of the existence of these instincts because they process information effortlessly and automatically and structure our thought so powerfully so that we take normal behavior for granted. This “instinct blindness” which he referred to as making the “natural seem strange” makes the study of psychology difficult. As a result psychologists have neglected to study some of the most interesting machinery in the human mind.

The Standard Social Science Model

Both before and after Darwin, there is a consensus view among scientists and philosophers that the human mind resembles a blank slate, virtually free of content until written on by the hand of experience (James 1890).

This concept that mind is a blank slate has changed over time from blank slate to switchboard to general purpose computer. It is considered that the architecture of the mind that has evolved consists of small number of general purpose mechanisms that are content independent, namely, learning intelligence, imitation, rationality, and culture, while the remaining human mind derives from the environment and social learning. Thus it states that there are the same mechanisms for learning language or recognizing emotional expressions or how one thinks about incest. It

also believes that all that we feel or believe is derived from social learning or environment. As per this model, the architecture of the mind has no role to play; it is only the external world that plays a role.

With improved research and progress in cognitive psychology, evolutionary biology, and neuroscience, it has shown that this concept is not correct stating that human mind is not a blank slate. The alternative view given by evolutionary psychologists states that over time the human mind develops regulatory circuits which are specialized in function and these functions are domain specific. The way we interpret experiences and add meaning to the intentions and actions of others is based on these circuits. It is also believed that all humans share certain views and assumptions about the nature of the world and human action by virtue of these human universal reasoning circuits.

Basic Principles of Evolutionary Psychology

Evolutionary psychologists believe that psychology is a branch of biology that tries to study the brain, how information is processed in the brain, and how behavior is generated by information processing programs in the brain. As psychology is a branch of biology, then the theories, principles, and observations of biology can be applied to understand the human brain. The five principles of biology can be applied to understand the human mind which helps to see connections between vision, reasoning, and sexuality. The five principles as given by Cosmides and Tooby (1997) are described below:

Principle 1. The brain is a physical system. It functions as a computer. Its circuits are designed to generate behavior that is appropriate to your environmental circumstances.

The first principle says that brain is just like a computer, and its functions are governed by similar laws of chemistry and physics just like computer. The difference is that the brain is made of organic compounds, while the computer is made of silicon chips. This means that chemical reactions in the brain produce thoughts, hopes, dreams, and feelings. The

information in the brain is transmitted through neurons which are known as electrochemical reactions. Just like the computer, the brain also has circuits in the form of different neurons which are connected in an organized way and determine how the information is processed in the brain. The behavior is generated by these circuits of the brain in response to the information from the environment.

Principle 2. Our neural circuits were designed by natural selection to solve problems that our ancestors faced during our species' evolutionary history.

Computers are designed by human engineers, so they can program a certain function which is suitable for solving a particular problem, but with brains, it is not designed by any engineer. The programming of the brain is designed by evolutionary process. The process that is most applicable here is natural selection. It means that those behaviors that resulted in better solving the problems which our ancestors faced were programmed. These circuits helped in the survival of our ancestors. The computational system of the brain is developed naturally, and it consists of all the circuits whose function is to solve adaptive information processing problems.

These circuits are designed to solve adaptive problems only which have occurred again and again in the history of evolution and their solutions have affected the number of offspring produced. Any circuit which reduces the reproductive rate of an organism will gradually disappear. Only those circuits which result in solving adaptive problem get designed by natural selection.

Principle 3. Consciousness is just the tip of the iceberg; most of what goes on in your mind is hidden from you. As a result, your conscious experience can mislead you into thinking that our circuitry is simpler than it really is. Most problems that you experience as easy to solve are very difficult to solve – they require very complicated neural circuitry.

The superficial simplicity of any bodily function can deceive us as it could be the response of many different stimuli which are

working together in the hind side which are not controlled by us consciously. The experience of seeing something is in itself so complex and involves so many different parts of the body that is hard to imagine that it could be so complex. The eyes capture rays which are printed on the retina in 2D form which is further converted in a 3D image with the help of specified neural network dedicated for the function of seeing any object in its physical form not as a piece of 2D drawing. Therefore it is with our concise experience we are able to evaluate only cream of conclusions rather than the thousands of specifically dedicated mechanism involved in gathering, analyzing, and evaluating information along with counterchecking for mistakes, filling any missing information, and making final conclusion.

Principle 4. Different neural circuits are specialized for solving different adaptive problems.

A solution to one problem need not be the answer to the second problem; the same can be said about the function of the human brain. The neural network dedicated for one task may not be able to solve the problem aroused in some other field, for example, the network dedicated for seeing an object cannot hear what sound that object is producing or even smell it. In order to hear, see, or smell, different neural networks are involved which can be visualized as a minicomputer dedicated to solve a specific problem. However, the evolutionary perspective suggests that most of the biological systems are calibrated to a specific environment, for example, the grass will always appear green no matter what the spectral timing of the sun is. Most of the rational algorithm for response is content independent as Bayes' rule does not have domain explicit knowledge, therefore it cannot be applied to inference of two different selection. Different problems require different solutions as the solution applicable for a living thing may not be applicable to a nonliving thing.

Principle 5. Our modern skulls house a Stone Age mind.

To survive in an environment requires a specified brain design which was governed by

natural selection; it takes a very long time to develop a neural network that is suited for a known environment. The neural network development process is so slow that we can say our modern skulls house a Stone Age mind, as the neural networks are not designed to solve modern day-to-day problems. The Stone Age neural network works better at some problems such as fear of snake in comparison to fear of electric shock. Despite being a Stone Age neural network, our mind can be compared to a highly sophisticated problem in which a network is designed to face problem faced by our ancestors on a daily basis.

Scope

Evolutionary Psychology Provides the Needed Causal and Explanatory Bridge from Evolutionary Theory to Manifest Behavior

Tooby and Cosmides (1989) provide the missing link between evolutionary theory and manifest behavior. It has further reinforced the importance of innate psychological mechanisms which are shaped or influenced by the evolutionary processes and are transmitted from one generation to the next. Structures of these innate psychological mechanisms influence the manifest behavior within a generation. It emphasizes that innate psychological mechanisms are the focal point of any evolutionary analysis of behavior. Adaptationist logic leads to characterization of modern behavior as either adaptive or maladaptive based on the principle of fitness maximization model, whereas evolutionary psychology focuses on knowledge of the innate psychological mechanisms that actually predict behavior more closely and it provides a unified core of models which assimilates the phenomena drawn from social science, psychology, anthropology, etc. According to Tooby and Cosmides, evolutionary psychology allows a new validating model to analyze the modern behavior. By including economic, cultural, and social factors into evolutionary algorithms, the modern behavior can be better explained not merely as an adaptive or maladaptive phenomenon but as an outcome of

development of the human mind and external conditions that are acting as an input for the architecture of the mind.

The Method of Evolutionary Psychology

As per the principles mentioned above, some guidelines in terms of to carry out research in the area of evolutionary psychology were proposed by Tooby and Cosmides (1989), which can be briefly described as the following:

1. In order to cultivate any model considering adaptive problem in which psyche of a person is involved, the starting point of model development should be an evolutionary theory.
2. Any adaptive problem manifested is directly related to close environment such as social, ecological, genetics, and physical situation, and it should be specified in details as this information contains information related to solve the problem. The building of a cognitive program should be such as it will guide behavior as per the adaptive path based only on the information provided to it in Pleistocene condition.
3. The adaptive model problem should be integrated to existing information of the relevant Pleistocene conditions, in order to derive any valid and useful inferences from current set of constraints. The specific information processing problem should be chronologically sequenced, which must be solved in order to achieve adaptive function. The computational theory will be further used to generate hypotheses related to cognitive programing structure needed to solve the adaptive problems in the question.
4. The computational theory will be used to determine whether there is any design feature in cognitive program for solving adaptive problem and also creating and improving candidate models of cognitive programs that might have been evolved in humans to solve a particular adaptive problem. It must be made sure that the model should be powerful enough in principle to realize the computational theory.

5. The alternative candidate models should be eliminated based on experiments and field observation, as the extensive methods developed by cognitive psychologists to track complex information should be taken full advantage. In the end a validated model for a cognitive program in question along with model environmental information is available for further studies.
6. Lastly a comparison should be drawn between models against behaviors that are produced by modern condition. Input from modern environment should produce behavior by the cognitive model already developed.

Cultural Universals

Cultural universals are traits or complex present in all individuals, all societies, all cultures, or all languages – provided that the trait is not too anatomical or physiological or too remote from the higher mental functions (Brown 1991). For example, myths, legends, rules, daily routines in the cultural realm; all languages consists of phonemes, morphemes, syntax, antonyms; and gestures, aggression, facial expressions in the behavioral realm. Many of the universals do not exclusively exist in one realm, e.g., the kinship terminologies in English like father, mother, brother, sister, etc. fall in the social, cultural, and linguistic realm. Another universal revenge is both behavioral and social.

Universals can be distinguished as either *emic* or *etic*. They are derived from the English words – phonemic and phonetic. The *etic* approach assumes that the features studied in one culture have significance in all cultures, while the *emic* culture assumes that cultural norms are specific to one culture only. For example, grammar is an *etic* fact, i.e., all individuals or cultures have grammar as part of language, but not all peoples have an overt cultural representation of the idea of grammar.

Some of the features of universals are as follows: a universal can be further subdivided like facial expression being universal. Further its

variations like smile and other expressions are also universal. Universals are simple as well as complex. Some universals are complex rather than being referred to as individual, for example, all cultures have music and dance, but not all individuals know dance or music. Universals can also be present only in one sex or in all individuals of particular age ranges.

There are some universals which are features of the human mind like the language acquisition device (as described by the linguist Noam Chomsky), emotions, classification, and psychological defense mechanisms. We are better able to understand the psychological mechanisms with psychobiology and evolutionary psychology. Psychology has been said to be majorly influenced by biology; thus the theories of evolution can also be applied to psychology presupposing universality of psychological mechanisms. Cognitive science considers the human mind to be like a computer which again believes that the psychological processes are universal. Thus it can be said that the psychological mechanisms are universal indicating psychic unity of mankind.

Conclusion

Humans are cultural species, and therefore psychological processes in humans have been found to be influenced by cultural variations. Cultural evolution incorporates evolutionary principles for understanding the cultural variations and transmissions in humans and other species. Traditional anthropology and social science theories view cultural evolution and transmission from the perspective of adaptational theory facilitated by the unitary principle of learning. Culture is generated through the rich and intricate human psychological mechanism which includes learning mechanisms that govern the cultural dynamics. In order to understand cultural processes, the processes and properties of complex and specialized innate psychological mechanisms acquire the center stage. Evolutionary psychology gives a new and promising approach for research on the structure of human mind incorporating the

knowledge and principles from evolutionary biology. By the pioneer work of Leda Cosmides and John Tooby, the basic principle and guidelines for conducting research in this area have been proposed. Though evolutionary psychology is in its infancy stage, it is expected that the advancements/growth in this field will provide us a more comprehensive model of the innate mechanisms of human psyche.

Definition

Evolutionary forensic psychology is the study of the evolved psychological mechanisms that give rise to thoughts, emotions, and behaviors underlying crime and forensic-related issues.

Introduction

This entry explores some of the insights and research that an evolutionary psychological perspective has generated around forensic-related issues. Emerging from theory and research in this area is an evolutionary forensic psychology literature that provides a unique and powerful understanding of the frequency of crimes, who is likely to commit crimes, and environmental and social factors that increase the likelihood of crime (Duntley and Shackelford 2008). A particularly influential aspect of evolutionary forensic psychology is that it provides a foundation rooted in the principles of the life sciences to understand forensic-related issues, allowing it to address ultimate as well as proximate causes of criminal behavior. The former refers to long-term historical and/or evolutionary explanations of why criminal behavior occurs, while the latter refer to short-term developmental and/or social explanations

Evolutionary Forensic

► Evolutionary Criminology

of how criminal behavior is caused (Tooby and Cosmides 1992). Thus, one of the strengths in using an evolutionary forensic psychology perspective is that it allows for answering questions about *why* we even have forensic issues. Why is crime and criminal behavior the way it is and not some other way (Pinker 2012)? An evolutionary view of crime allows us to question the very assumptions about what constitutes crime and our responses to it.

In this entry, we briefly outline how evolution informs us that the very notions of “crime” and “law” reflect our moral impulses as a species. We will then offer a preliminary exploration of the interface between nature and nurture before examining how a focus on individual differences (i.e., personality) reveals their interaction. Regarding personality, we will cover broader personality traits before turning toward a look at the specific personality type that is most strongly associated with criminality: psychopathy. Finally, we turn from these person-based views toward studying two examples of a more behaviorally oriented view that focuses on two salient and consequential categories of criminal behavior: homicide and sexual crimes. We will pay particular attention to why these crimes are prevalent in specific contexts that an evolutionary perspective frames for us.

“Law” and “Crime” as Reflecting Moral Impulses

Where does our society’s notion of what constitutes a “crime” come from? Why do we have a “law” that most people want to uphold? These are questions rarely asked outside of an evolutionary forensic context, but they formulate the very basis for understanding and even having a criminal justice system (Walsh 2000). It might seem obvious and even odd to point out, but notions of crime and the law are mental constructs that are rooted in our moral impulses of what is right and wrong, fair and unfair, and just and unjust (Haidt 2001). They exist and have their origins in our minds, and yet they structure society, regulating and governing behavior both implicitly and explicitly.

What we deem as criminal behavior is thus a complex interface between evolved and/or historical predispositions along with more recent societal norms and values (Pinker 2012).

In the context of this interface, moral impulses describe thoughts and feelings that underlie our sense of right and wrong, fairness, and justice (Haidt 2001; Krebs 2008). What happens to your mind and body when you observe a child being harmed? How does this change if it is an adult stranger harming a child compared to if another child is the one doing the harm? The thoughts and feelings that emerge upon viewing the harmed child and the context that surrounds the harming *are* the moral impulses in action. The point made from an evolutionary forensic psychology perspective is that the “law” itself and its “crimes” are often a result of these moral impulses being activated, thought-about, and written down in response to actions that elicit them (Daly and Wilson 1988; Duntley and Shackelford 2008).

These types of actions that activate our moral impulses have fitness consequences (Krebs 2008; Walsh 2000). This is the main evolutionary argument for why we experience negative affective reactions toward criminal behavior, because the costs they instill are so large (Daly and Wilson 1988). When thinking about cheaters anywhere from tax evaders to thieves, the benefits accrue for individuals at the expense of the common good and social order (Joyce 2007; Krebs 2008). Thus, in these instances where the law creates crimes that are unlawful, we see moral impulses framing our attention in their direction, and the attention is being drawn there by the forces of evolution over previous human (and prehuman) generations. On the other hand, the cultural evolution of justice systems, state punishment, and common moral values has also had an important influence on the execution of moral impulses in modern society (Pinker 2012).

Adaptive Criminal Calibration

This interaction of nature and nurture reflects a persistent question regarding behavior: Which is more important, biological predispositions or

environmental influences (Ellis et al. 2012)? The answer is neither. Much like one needs both chocolate and an oven to make chocolate cake, behavior is a product of the interaction between environments and biological predispositions (Ellis et al. 2012; Kim-Cohen et al. 2006). In this light, an individual who displays antisocial tendencies may not be expressing a maladaptive or “broken” pattern of development (Ellis et al. 2012). Rather, they may be displaying a specific adaptation toward environmental circumstances that better guide their development toward behavior that will be adaptive under those environmental conditions (Lalumière et al. 2005). For example, exposure to violence has been shown to associate with an improved memory for some details (e.g., dominance) that might represent important evolutionary outcomes (Frankenhuis et al. 2019). Individuals raised in an environment that values aggression and fearlessness may well reward violent behavior under the right circumstances (Chagnon 2013; Mealey 1995).

Fortunately, as mentioned above, we can alter the environment so as to change the costs and benefits of criminal behavior in ways that make it less appealing and prevalent (Barr and Quinsey 2004; Pinker 2012). We strongly emphasize that any biological predispositions for criminal behavior should not be viewed as biologically predetermined, unresponsive to environmental factors, or morally sanctioned by evolutionary principles. Indeed, there may be instances where the commission of criminal behavior represents the maladaptive expression of a more modest adaptation. For instance, circumstances could lead an incidence of bullying (a generally adaptive aggressive behavior; Volk et al. 2012) to escalate into an unintended homicide, which would be labelled a maladaptive by-product of bullying (Daly and Wilson 1988; see section “[Is Homicide an Instance of Adaptation?](#)”). Thus, an evolutionary view of forensic psychology is not deterministic, or offering moral value to “natural” behavior, but instead examines the role of evolved predispositions as one of many interactive factors causing criminal behavior. Instead, the knowledge of any such predispositions affords information about how to best alter, reduce, and/or prevent

the expression of those predispositions. To best make effective alterations (e.g., interventions, social policies, and laws), we should therefore understand the underlying preferences and predispositions that could encourage the development and expression of criminal behavior (Ellis et al. 2012). We will bear forth this interactive view as we examine two of the more common individual factors that may influence criminal behavior: general personality (i.e., the HEXACO) and specific antisocial personality (i.e., psychopathy).

Personality and Crime: A Focus on Individual Differences

With a focus on individual differences, personality has a fundamental role to play in the evolution of antisocial and criminal behavior. Trait-based personality items have the potential to represent heritable individual differences that can differentially relate to adaptive outcomes in different environments (Buss and Hawley 2010). While there are numerous specific personality types associated with forensic psychology (e.g., psychopathy, narcissism, borderline personality, Machiavellianism, sadism, etc.), the origins of these varying types of personality quickly present a large number of requisite unique adaptations required to explain their existence. What may be more plausible – and both useful and parsimonious to know – is that a smaller range of personality traits may have evolved that can be tweaked given environmental input to produce varying adaptive outcomes. Some have suggested that the Dark Triad of psychopathy, narcissism, and Machiavellianism represents just such a more unified cluster of adaptive personality traits with the idea being that all three types of personality share a common core of antisocial personality (Paulhus and Williams 2002). Intriguingly, the core of these variables may be the personality trait Honesty-Humility, from the HEXACO model of general personality, with its negative pole showing an almost perfect match to the core of the Dark Triad ($r = -0.95$; Hodson et al. 2018). Honesty-Humility represents a general tendency to exploit

others for one's own benefit (Ashton and Lee 2007) that may well underlie the general tendency for individuals to invest and act in their own self-interest, producing much of the crime in society.

The advantage of having a general model of personality like the HEXACO as the foundation of forensic personality psychology is that it not only connects forensic applications of personality with more general applications of personality, but it also does not require the creation of adaptive evolutionary scenarios for each type of forensic personality. Instead, one simply has to dial up or down various combinations of the six factors of the HEXACO to obtain varying forensic personality types (Ashton and Lee 2007). For example, Machiavellian personality may be associated with lower Honesty-Humility and lower Agreeableness (i.e., lower patience and forgivingness). Psychopathic personality may have similar negative correlations, but with the addition of negative correlations with Emotionality (i.e., lower sentimentality and anxiety) and Conscientiousness (i.e., lower impulse control and planning). This makes the HEXACO much more plausible evolutionarily and developmentally, as it requires genetic ties to only six traits that are presumably present in virtually all normally developing humans. The cross-cultural validity of the HEXACO further enhances this plausibility (Ashton and Lee 2007), as does the fact that the HEXACO cleanly lines up with a unique genetic factor for each factor (Lewis and Bates 2014). Thus, the HEXACO offers the potential for parsimoniously explaining not just general personality from an adaptive, evolutionary perspective, but it may also serve as a useful tool for studying the evolution of forensic personality types. Indeed, in surveys of male convicts, the HEXACO accounted for almost half of the variance in self-reported antisocial behavior, making it a valuable tool for use with forensic populations (Mededović 2017).

In summary, personality traits, and the HEXACO model in particular, may present a useful and parsimonious way of understanding person-level risk factors in engaging in antisocial and criminal behavior. These personality traits

should be conceptualized not as inborn tendencies, but rather inherited predispositions being shaped through life experience to produce personality orientations that attempt to optimize survival and reproductive gains.

Psychopathy: A Forensic-Revealed Adaptation?

While the HEXACO represents a broad measure with similarly broad validity, there may be more specific measures of antisociality that account for even more variance with respect to criminal behavior (Harris et al. 2015; Mededović 2017). Psychopathy is a set of personality and behavioral traits that are related to a number of socially undesirable and adverse outcomes, foremost being involvement with crime (e.g., Hare 2003). Traits fall broadly into two categories labelled as Factor 1 and Factor 2. Factor 1 is comprised of interpersonal and affective characteristics, including manipulativeness, superficial charm, and a profound lack of empathy and remorse. Factor 2, on the other hand, contains more behavioral features, including a tendency for impulsivity, irresponsibility, and having poor behavioral controls and aggression.

Individuals with psychopathic traits are more likely to engage in criminal behaviors and are much more likely to reoffend after release. In fact, psychopathy is the single best predictor of violent recidivism (Harris et al. 2015). Research consistently finds heritability around 50% (for a full review, see Glenn et al. 2011), and multiple researchers have suggested that psychopathy, rather than being a "disorder," may be an evolutionary adaptation designed to exploit others (e.g., Barr and Quinsey 2004; Mealey 1995).

For a trait or constellation of traits to be considered an adaptation, it must have conferred relative benefits in facilitating survival and/or reproductive success (Andrews et al. 2002). Importantly, psychopathy is not associated with "neurodevelopmental perturbations" that would normally accompany a disorder, including fluctuating asymmetry, obstetric complications, and comorbidity with mental disorders (Lalumière

et al. 2005). In terms of being related to reproductive success, psychopathy has been found to be related to the tendency to engage in a fast life history strategy (one emphasizing short-term mating effort, increased risk taking, and selfish exploitation) (Barr and Quinsey 2004). For example, people with psychopathic traits have earlier sexual experiences and are more promiscuous and engage in more short-term marital relationships, which also constitute two items on the Psychopathy Checklist-Revised (Hare 2003). Further, research finds that those higher in psychopathy have as many (or more) children compared to those lower in psychopathy (Mealey 1995). Interestingly, offenders manifesting more psychopathic traits appear less likely to victimize kin in their crimes, which supports psychopathy being selected based on the principles of inclusive fitness (Krupp et al. 2012).

Many of the researchers who take an adaptationist perspective focus on the exploitative nature of psychopathy. These researchers have suggested that psychopathy may be an adaptation for social predation/exploitation (e.g., Mealey 1995), and early descriptions of psychopaths highlight their exploitative nature (e.g., Cleckley 1976). Empirical research supports the assertion that psychopaths do tend to exploit and manipulate others and use deception across numerous social contexts (Jonason and Webster 2012). As well as being deceptive and manipulative, psychopaths are impulsive and aggressive (Hare 2003), using such strategies to get what they want from others. The combination of exploitativeness and aggression as a strategy has been coined the “Cheater-Hawk Hypothesis” (Book et al. 2015).

Frank (1988) suggested that a successful opportunist should be able to judge vulnerability in others and also to avoid detection. Early anecdotal descriptions of psychopaths suggest that they are able to judge vulnerability in others (Cleckley 1976), and empirical research suggests that people with psychopathic traits are able to judge victim-related traits, such as assertiveness and vulnerability, from body language (Book et al. 2013). As well, Jones (2014) suggested that psychopaths engage in short-term strategies

involving social mimicry to acquire resources and that this represents how they avoid detection. We know from previous research (discussed above) that psychopaths use deception and manipulation across many contexts. Another important part of social mimicry involves feigned emotional states, and there is some empirical support for the idea that psychopathic individuals are able to feign basic emotions such as fear and social emotions including remorse (Book et al. 2015).

To summarize so far, there is some evidence and support for the idea that psychopathy is an adaptation for social predation and exploitation of some kind, but the nature of that adaptation is yet unclear. Commonalities across most adaptation hypotheses of psychopathy suggest sex (i.e., being male) was important in selecting for psychopathy as was a short-term exploitative strategy that may have ensured reproductive success (Mealey 1995). While less research has focused specifically on the “special design” features of psychopathy (Krupp et al. 2012; cf. Brazil and Forth 2019), two broader-level evolutionary models have been proposed that support psychopathy fitting an evolved reproductive strategy (Glenn et al. 2011).

The first model is known as *balancing selection*, which suggests that psychopathy would have been shaped for its fitness advantage in the ancestral environment as an alternative reproductive strategy (Glenn et al. 2011). One potential balancing selection model to explain psychopathy is *frequency-dependent selection* (e.g., Barr and Quinsey 2004; Mealey 1995). In this model, psychopathy is maintained at a consistently low ratio in the population, an expectation that is supported by the low prevalence of psychopathy (at or around 1% of the general population; Hare 2003). This model is supported by computer simulations showing that “cheating” is only an evolutionarily stable strategy when it exists at low frequencies (Dawkins 1976). Presumably, when the frequency of cheating is too high, there is heightened risk of interacting with other cheaters which would obviously reduce the effectiveness of the cheating strategy. This low frequency needs to

be accounted for in models describing the evolution of psychopathy.

While balancing selection does account for the low prevalence of psychopathic traits in the population, there are environmental conditions that differ over both time and place in effecting the expression of psychopathy. Another model that attempts to deal with these conditions in explaining psychopathy as an adaptation is contingent shifts. In *contingent shifts* “psychopathic traits are an adaptive response to specific environmental conditions” (Glenn et al. 2011, p. 371). In this model, the level of psychopathic traits expressed in a population would differ depending on the environmental context and its tendency to provide benefits that outweigh the costs of manifesting the traits. In other words, there may be certain environments that encourage the expression (and, alternatively, discourage the expression) of psychopathic traits; costs and benefits are weighed according to this model, and sometimes the benefits are high for psychopathic traits that gives them a fitness payoff. A good example would be the effect of parenting style and attachment on the expression of psychopathic traits. In children who have the capacity to develop these traits, abuse or neglect may “unlock” them during development, making them respond flexibly and adaptively to the conditions to ensure chances of survival and reproduction.

Importantly, balancing selection and contingent shifts models are not mutually exclusive. This means that psychopathy may have been selected and maintained in the population over human history based on a combination of these models. Uncovering and testing the “special design” features of psychopathy and continual research into its potential as a forensic-revealed adaptation will provide more information about these models in explaining psychopathy from an evolutionary perspective. With this coverage of individual differences in light of forensic-related issues, we now focus on criminal behaviors of homicide and sexual crimes that an evolutionary forensic psychology perspective emphasizes, further illustrating the interface between nature and nurture in producing crime.

Homicide

Just over half a million homicides occur every year around the globe (Krug et al. 2002), which is likely an underestimate due to misreported and undocumented homicides. Homicide is one action that can inflict the ultimate fitness cost on the victim, making it a plausible strategy for eliminating fitness competitors and a clear behavior that evolutionary researchers need to contend with (Duntley and Buss 2011), and it has been argued that an evolutionary lens can enhance our ability to understand the underpinnings of homicide (Liddle et al. 2012). We should note that not every homicide need be adaptive, and some have argued that some cases of homicides may be the by-product of more modest adaptive predispositions (e.g., an adaptive tendency toward mate guarding could escalate into a maladaptive case of homicide; Daly and Wilson 1988). While differentiating between adaptive and by-product behaviors is beyond the scope of the current manuscript (e.g., Durrant and Haig 2001; Sosis 2009; Tooby and Cosmides 1992), we offer the opinion that the difference between the two can at some level be semantic as many of the underlying evolutionary pressures are similar. In either case, evolutionary theories generate hypotheses that can test between these two levels of explanations. For that reason, we will focus primarily on adaptive explanations of criminal behavior.

We can also appreciate why certain types of homicides are likely to be committed by men and women differently, at different times during one's lifetime, and differently depending on one's life circumstances. An evolutionary forensic psychology perspective enables an explanation of why certain patterns of homicide occur and what conditions enhance the likelihood of homicide. Martin Daly and Margo Wilson's book *Homicide* (1988) influenced evolutionary forensic psychology and provided one of the first comprehensive studies of behavior and psychology using the lens of evolution. They demonstrated how homicide committed by men and women should differ due to differing adaptive problems faced by the sexes over evolutionary time and that different types of homicides should expectedly emerge in

different social contexts that may reflect solutions to adaptive problems.

Homicide Committed by Men

At first blush, homicide may seem to be an entirely male endeavor. This is far from being true, and we will also describe some of the instances when women kill, but it is not an overstatement to claim that men are disproportionately involved in homicides – as both perpetrators and victims (Daly and Wilson 1988; Krug et al. 2002). In a study of Detroit homicides, it was shown that just over 82% of homicides were committed by male perpetrators. Of these homicides committed by men, just over 82% had a male victim (Daly and Wilson 1988). This means males were disproportionately responsible for killing others, and they were disproportionately killing other men. Krug et al. (2002) also found that around the globe, 78% of homicides were committed by men. (These findings may suggest homicide falls under a “four-fifths effect,” whereby men are killing and being killed by other men in four-fifths of all homicides.) Another factor is that the vast majority of those both killing and being killed were young men, with the risk of being involved in homicide decreasing as one aged. This led to the proposition that the competitive and risk-taking traits underlying violence and homicide might be called a “young male syndrome” (Daly and Wilson 1988).

Not all young men, however, are involved in committing such fatal violence. Two additional risk factors increased the chances of a young man being involved in such violent altercations: (1) being unemployed and (2) being unmarried (Daly and Wilson 1988; Krug et al. 2002). From an evolutionary perspective, these two factors are expected to increase a male’s propensity to engage in competitive violence since they touch on the variance in male reproductive success and on having access to resources (Geary 2010). Unemployment indicates lacking resources and having low prospects for the future, while being unmarried may indicate that the man is without a long-term partner and thus unlikely to reproduce. Being unmarried certainly does not preclude having other sexual relationships (and potentially

children), but it may signal to the young man that they are not desirable as a long-term partner, and this may have a strong influence on the evolved psychological mechanisms in orchestrating the competitive behavior of these young men.

An evolutionary approach to studying violence in general and homicide more specifically requires examining context in order to ascertain the “specific inputs that are likely to activate the psychological mechanisms that generate violent behaviors” (Liddle et al. 2012, p. 33). Evolutionary theory has led to the collection of strong empirical evidence that as economic inequality increases, so too do male-male violence and homicide (Daly 2016). This pattern of findings appears consistent across a number of countries for which data are available, suggesting that economic inequality may, or should, be thought of as a potential *cause* of male-male violence and homicide (Daly 2016). That male reproductive success is more highly variable compared to females suggests this inequality may have differing adaptive consequences across the sexes (Daly and Wilson 1988; Duntley and Buss 2008). A competitive arena where some males have (reproductive) success and many lose out may breed competition among men, often escalating to violence and homicide in men’s attempts to garner resources and status (Betzig 1982). This perspective allows for making predictions about what social and economic circumstances should give rise to male-male violence and homicide. More egalitarian and equitably distributed societies should be expected to engage in less male-male violence, a contention that has some support from anthropological research (e.g., Friedl 1978).

In conclusion, when it comes to understanding an evolutionary perspective of homicide regarding men specifically, one should consider the degree to which boys and young men are growing up in an environment that fosters and is structured by competition that has differential outcomes for its participants (Daly 2016). The greater the difference in experiencing either reward or loss and thus being a big winner or big loser, the greater seems to be the likelihood of men engaging in violence that can progress to fatalities (Betzig 1982). This seemingly simple observation is

borne out by evidence from around the globe that was facilitated by using an evolutionary forensic psychology perspective of the problem of homicide and points to the usefulness in using such a perspective when trying to understand complex social problems.

Homicide Committed by Women

Women's involvement with homicide differs starkly from men's involvement facilitated by competitive environments. There are primarily two instances where women are occasionally engaging in homicide: (1) killing newborn children and (2) killing their spouses (Daly and Wilson 1988). Even though women are not showing up in police records in high numbers for these crimes, these two instances represent evolutionarily expected instances of women deciding to engage in violent fatalities. They may represent extreme measures taken at an instance in time in the woman's life where a threat to her survival is evident. In the instance of killing spouses, women are often killing their male partners when the male partner is threatening her life or in an instance of infidelity. When killing her child, a woman may be making such a decision not as a remorseless psychopath but instead based on difficult and particular life circumstances that suggest she is engaging in adaptive decision-making influenced by harsh realities (Hrdy 1999). This is not to excuse such actions, but it does help in understanding why women decide to kill their offspring, and it gives researchers a means by which to promote alternative circumstances to what women at risk tend to experience. The presence of two such circumstances, young age and not having a committed partner, influences whether a woman may be at risk of infanticide, both historically and in modern contexts (Daly and Wilson 1988; Hrdy 1999).

Because women are disproportionately responsible (physiologically, psychologically, and socially) for the upbringing of children, investment decisions can be a high-stakes matter. If current circumstances and prospects appear grim for a woman to raise healthy offspring, she may begin to consider fatal alternatives that will not compromise her future chances of reproductive

success (Hrdy 1999). Because younger women have higher reproductive potential (ability to bear more future offspring), there may be less of a cost to infanticide since future reproductive potential would be higher for them. This helps make sense of why women committing infanticide in these early years are not necessarily at risk to do so later in life (Daly and Wilson 1988). The young mother may also currently be in less of a position to provide the appropriate investment care in her offspring to guarantee their survival. In societies where state-supported child care is absent and a child's survival depends mostly on the mother, the decision to kill offspring becomes less morally intertwining and more based on harsh realities (Hrdy 1999).

The emphasis on biparental care in humans may explain why lacking a long-term partnership may be a risk factor for infanticide (Daly and Wilson 1988). Even if not direct biparental care, human mothers often depend on raising offspring with at least the indirect help of fathers in the form of security or material resources (e.g., Hewlett and Macfarlan 2010). In the absence of any extra social support from a male partner, new mothers appear at an increased risk of infanticide. Again, this appears to be a decision that is made by women surveying their environment when making investment decisions in their offspring's development. In the occasions where a partner is absent (and especially if other social support including extended family is also absent; Hrdy 1999), her risk of killing her child may increase due to the investment payoff lessening. Though the emotionally evocative nature of infanticide can be overwhelming, it is not surprising when taking an evolutionary forensic psychology perspective why women engage in this behavior.

Types of Homicide

There are a number of homicide typologies that have emerged over the years (e.g., Daly and Wilson 1988). These typologies attempt to cluster together similar types of homicides in seeking to understand and potentially prevent similar homicides from occurring in the future. Most existing typologies, however, do not consider an evolutionary framework to classify homicides making

them relatively more subject to author/researcher bias in terms of how they get clustered together. An example of this is the category “intimates” whereby spouses, family members, and close friends are considered together in one group or another where “family” consists of both spouses, biological kin, and non-related kin or step relations (Daly and Wilson 1988). An evolutionary forensic typology of homicide, however, would be sensitive to whether victim-offender relationships have genetic relatedness as in the case of biological children and siblings compared to step relations such as stepparents or stepchildren. Homicide records should show less closely related victim-offender observations because of the evolutionary principles of genetic relatedness and inclusive fitness (Hamilton 1964). Across multiple cultures, this appears to be the case, with the vast majority of homicides involving “family” and “intimates” actually showing that the victim or offender are non-related kin or spouses rather than biologically related kin (Duntley and Buss 2008). This also happens to be the case for killing infants and young children, where there is approximately a 100-fold increased risk of a child being abused or killed when there is at least one stepparent in the household (Daly and Wilson 1988).

Another typology that has become clarified and comprehensible with the inclusion of an evolutionary forensic psychology perspective is male-male violence that escalates to homicide. In the past, these forms of homicide have been described as “trivial” altercations between men, no doubt with the assumption that these men lacked rationality and emotion regulation skills to keep their passions in check. While this may be true, this is merely descriptive and not explanatory. Why men from cultures around the world should engage in escalating violence due to “trivial” matters is made comprehensible by an evolutionary perspective that focuses on how social competition has reproductive consequences (Betzig 1982; Daly and Wilson 1988).

“Social conflict homicides” is an atheoretical accumulation of homicides involving business, jealousy, family, and friends. What may be surprising from this atheoretical perspective,

however, is that more than half of social conflict homicides involve “trivial altercations” between men (Daly and Wilson 1988, p. 63). An evolutionary forensic psychology perspective sees these altercations as evolutionarily consequential and thus allows us to understand them as instances of “saving face” or generating respect in one’s social group. This is not to excuse the actions involved in these social conflicts, but it does help us understand why men can become psychologically convinced that responding to the escalating social conflict with fatal violence is the only option available to them and why these are the most common of the social conflict homicides.

While many male-male homicides seem to fall into the typology of “trivial altercations,” other social conflict homicides involving male-male altercations including sexual jealousy homicides and revenge homicides may share similar motives (Duntley and Buss 2011). These motives revolve around acquiring and maintaining group respect within a status hierarchy, attracting opposite-sex mates, and ensuring paternity certainty. Intriguingly, but expectedly from an evolutionary view, these motives share in common ensuring the reproductive success of men within a social group. Men fight about status, and they fight about women, often with fatal consequences. There is little doubt that the *degree* to which this occurs depends on culture (e.g., Daly and Wilson 1988) but that it occurs across cultures around the world is of little doubt (e.g., Duntley and Buss 2008). From gangs in the United States to the Yanomamö tribes of what is now Brazil and Venezuela, men are ostensibly fighting and killing over status and women. These social conflicts have documented fitness consequences as well, whereby men who have killed in both US gangs (Duntley and Buss 2008) and the Yanomamö tribes (Chagnon 2013) each see their status and reproductive success increase afterward. These unusual findings of violence “paying off” are made clear when we have an evolutionary forensic psychology perspective directed at them. Indeed, in order to fully understand fatal violence and its motives, an evolutionary explanation seems necessary; otherwise, motives and behaviors get arbitrarily described as “trivial,” thus

giving the impression of being random and difficult to understand.

Is Homicide an Instance of Adaptation?

While there appear to be reproductive benefits to engaging in lethal violence as described above, does this entail there being underlying psychological mechanisms that have been shaped to execute homicidal thoughts and behaviors? Some researchers have argued that this is indeed the case (e.g., Duntley and Buss 2008, 2011), whereas others also see the possibility that homicide may be a by-product of escalating violence (e.g., Daly and Wilson 1988). We do not offer any attempt at a definitive answer here but instead focus on what it means to have adaptations for homicide. Further, we stress the need to consider context as environmental cues are clearly important for activating any psychological mechanisms that may generate violence (Liddle et al. 2012).

Having adaptations for homicide would indicate that humans have psychological mechanisms that produce phenotypic effects (thought patterns, emotions, behaviors) that have explicitly been shaped into our available heritable traits that provided relative fitness benefits (Duntley and Buss 2011). These should be thought of not as a single adaptation or module for homicide, but rather many possible modules that may have similarities but are differentially activated depending on contextual factors. For instance, a young mother that recently had her partner leave her and has dismal familial social support may have an infanticidal thoughts and behaviors mental module become more active, whereas a man who sees his partner with another man will have a sexual jealousy mental module activated. This perspective takes the contextual nature of homicides to its extreme and proposes that thoughts and behaviors related to killing are context-specific and should not occur outside of those contexts (Duntley and Buss 2011). That many of the homicides reported throughout this entry are context-specific is in line with this perspective (Liddle et al. 2012), but the scope and veracity of the idea of homicide adaptations are still in its infancy.

Sexual Crimes

What we are calling sexual crimes are behaviors between the sexes that the law defines as illegal and constitute some of the most cognitively and emotionally disturbing realities in society. These crimes include sexual harassment, rape, and intimate partner violence and are far more often committed against women by men (Daly and Wilson 1988). Additionally, we will describe the crime of prostitution, which in some jurisdictions is not considered a crime (Salmon 2008). Sexual crimes are some of the most easily understood crimes when using an evolutionary perspective, given their importance and consequences regarding reproductive success (Duntley and Shackelford 2008).

Sexual Harassment

There are broadly two types of sexual harassment. First, quid pro quo forms of sexual harassment involve acquiring benefits or avoiding costs contingent on performing sexual acts (Browne 2008). This is the classic case where usually male supervisors offer to promote a female subordinate on the condition that she engages in sexual activity with him or threatens to fire her if she does not. The second form of harassment is hostile environment harassment where the working environment is claimed to be overlaid with sexual insults, intimidation, and discrimination. This form of harassment is less directed at any particular individual but has the capacity to discriminate, intimidate, and unfairly influence certain individuals' experiences at work, especially young and attractive women (Browne 2008).

Why do men mostly engage in sexual harassment, whereas women are often, but not always, the targets? One common perception in non-evolutionarily informed social science research is that men use sexual harassment as a tool to reinforce and demonstrate their social positions of power (Browne 2008). An evolutionary perspective, however, enables us to move away from this unidirectional perspective and also see that men use their power to obtain sex. Referring back to Geary's (2010) suggestion that men's reproductive success is constrained by the number of

females they mate with allows us to understand the logic of selection pressures acting on men's minds to increase their number of mating partners when given the chance (i.e., when having the status and resources to do so). Across instances in history, men with an inordinate amount of power such as Genghis Khan and other despots have regularly used that power to acquire many sexual partners (Betzig 1982; Daly 2016), often leading to enormous reproductive success (e.g., Zerjal et al. 2003). Indeed, history seems to suggest that unyielding power in the hands of men reliably leads to their optimizing that power and influence for sexual gain. This has implications for policy such that an evolutionary view supports the notion that absolute power in the hands of few individuals – particularly men – is not a practice that workplaces should promote (Browne 2008).

Equally as important for understanding the evolutionary logic of sexual harassment is why women do not engage more in it. Again, referring to the idea that women are less likely to gain reproductively from acquiring additional sexual partners and that parental investment tends to be skewed toward females makes their involvement in sexual harassment less beneficial reproductively and thus less likely to occur (Geary 2010). This does not mean women cannot become tyrannical sexual harassers in the workplace, but it does indicate that women are far less likely to use their power and influence *for* sex. Instead, women may use sexual harassment strategically for career advancement or influencing their position in society, whereas men are likely to use sexual harassment *for* sex (Browne 2008).

Rape

Sexual coercion, or rape, is a difficult topic to discuss because of the emotional toll it causes victims and the morality surrounding such coercive actions. Nevertheless, a disturbingly high proportion of women (with some estimates as high as 13% in some US states) report experiencing rape at some point in their lives, with an especially high-risk during young adulthood when reproductive potential is highest (McKibbin et al. 2008). Additionally, sexual

coercion extends deep into our history as a species and across the globe (Lalumière et al. 2005). Rape victims are not exclusively female as many males experience sexual coercion as well, but the reality is most victims tend to be women and girls, while perpetrators tend to be men and sometimes boys. Corroborating that rape is committed mostly by men, some unsettling research show that many men report having coercive sexual fantasies and at least one-third say they could see themselves committing rape under specific conditions (Huppín and Malamuth 2016). Clearly, understanding the contexts under which men may become rapists and why this is the case is crucial for researchers and social policy.

What an evolutionary perspective adds to forensic research into rape is framing *why* some men come to commit such coercive actions and even why there is a cost, psychologically and reproductively, to women of such actions. An evolutionary perspective allows us to appreciate, beyond moral and emotional reactions to sexual coercion, the reasons why such actions are costly to women (McKibbin et al. 2008). However, it also frames an understanding of the potential benefits men may accrue from sexual coercion, hence why they may commit such actions. It should be noted that there is debate about whether rape should be considered an adaptation on its own or whether it is a by-product of the tendency to engage in sexual coercion, more generally (Thornhill and Palmer 2000).

For women, and from an evolutionary perspective, costs of rape are subversion of mate choice in whom she has offspring with, creating the possibility of becoming impregnated by a male that she otherwise would not want to have a child with (McKibbin et al. 2008). Women also face the evolutionary cost of being perceived as less desirable by some men if they have been raped by another man, which can limit her mate choice and future reproductive success (Huppín and Malamuth 2016). Lastly, and especially in foraging ancestral environments (e.g., Tooby and Cosmides 1992), rape may force women to experience the cost of investment in unwanted pregnancy that takes physiological and social

resources that are valuable and not unlimited away from other offspring investment (either in the future or her current children), potentially compromising her current and future reproductive success. For men, and from an evolutionary perspective, the benefits of rape are to potentially sire offspring without having to invest in courtship behaviors. Because males may benefit reproductively from accessing multiple females, one plausible way of acquiring extra mates may have been through coercion (Lalumière et al. 2005). Additionally, if reproductive success is skewed for males in a population, rape may become one method for attempting to reproduce. Thus, from an evolutionary perspective, rape provides a “solution” to the problem of overcoming the variance in male reproductive success, and this may be unique to specific kinds of men within their social hierarchies (e.g., Betzig 1982; Lalumière et al. 2005; McKibbin et al. 2008; Zerjal et al. 2003).

It is important to point out here that rape may not have had as much reproductive benefit for male ancestors as might be gleaned upon reading the paragraphs above. Counter-selection pressures (e.g., women’s fear of strange men, women’s protective bonds with others) and other selection pressures within males (e.g., for social emotions, bonding, paternal care) likely created ancestral environments where rape may not have reliably added to a male’s reproductive success. Instead, it may have occurred mostly as a response to particular conditions – wartime, societies with high male reproductive variance, and unstable male coalitions – whereby men perceived particularly opportunistic, anonymous, or dismal future conditions for themselves, making rape a “last resort” at reproduction (Lalumière et al. 2005). This suggests that halting the commission of rape in cultures around the world may require an appreciation for and understanding of the social and economic conditions that facilitate men’s propensity to engage in this behavior.

Intimate Partner Violence

Once in a relationship, it may seem that intersexual violence is likely to decline. While this is the case for many relationships, many others

experience domestic or intimate partner violence (Goetz et al. 2008). Intimate partner violence including verbal, emotional, and physical abuse of one’s partner occurs at a high rate in countries around the world. In the Yanomamö, men regularly hit their wives for the slightest of indiscretions, which often involve perceived flirtation on the part of the wife with another man in the group (Chagnon 2013). In Western countries, both sexes engage in intimate partner violence, but men tend to facilitate the abuse, and they tend to exact more severe abuse on their partners than do women (Daly and Wilson 1988; Goetz et al. 2008).

An evolutionary reading of intimate partner violence, particularly actions committed by men toward women, involves acknowledging the differences in the certainty of having a relationship to one’s offspring. Specifically, for men, there is always a component of uncertainty of his paternity regarding his children that a mother does not contend with. This has likely created an anxiety that selection has influenced in men’s phenotypes, making them more likely to experience sexual jealousy, be preoccupied with a partner’s (in)fidelity, and have feelings of sexual proprietariness toward their partner (Daly and Wilson 1988; Goetz et al. 2008). In other words, men’s minds have likely been shaped to more easily see women as property that needs to be guarded, and they are more likely to ruminate about their partner’s sexual intentions and actions (Duntley and Buss 2008). One possible consequence or shaping feature that selection may have instilled in the minds of men as a result of this paternity uncertainty is the behaviors they execute if they believe their partner has been unfaithful (Goetz et al. 2008). For instance, men may rape their wives if they believe they have been with another man, which, if they had been, may potentially displace the other man’s sperm. Another possible response is cordoning off his partner from friends and family to ensure she cannot be unfaithful again. Either way, these behaviors motivated by sexual jealousy and proprietariness that have an evolutionary logic cause substantial psychological and emotional abuse of women, making understanding them that much more important.

Prostitution

Often described as the world's oldest profession, prostitution constitutes an interesting example from both an evolutionary and legal perspective. From a legal perspective, some countries, and even within some states in the United States (e.g., Nevada), prostitution is not considered a criminal offense (Salmon 2008). In many other countries including Canada, it is not illegal to sell sexual services (i.e., to offer sex for money). In Canada though, prostitution legislation gets complicated because it is actually illegal to purchase these sexual services and it is illegal to advertise such services. These laws emerge from a long history of attempting (but failing) to curb the exchange of sex for resources and protect sex workers (who are mostly women) from abuse and criminal prosecution. That societies have laws and manifest such a stake in the sex lives of individuals reflects again the moral impulses that govern the laws and determine what constitutes a crime (Walsh 2000). Because of its connection to reproductive success, sexual activity of all kinds would have been highly regulated and monitored in ancestral environments, with modern environments being a predecessor of such conditions. Prostitution laws, being rooted in deeply moralistic reasoning, reflect this inheritance.

Who tends to purchase sex for money? Overwhelmingly, men are the clients, and they are often, but not exclusively, purchasing the sexual services of women, some of whom are street sex workers, but most (~75%) of whom are in-call or out-call sex workers (Salmon 2008). Why are men tending to be the purchasers and women the sellers? An evolutionary perspective suggests that because men have had a stronger history of selection toward sexual variety and obtaining multiple partners (e.g., Geary 2010), they should experience a stronger desire for sexual experiences that offer these potential reproductive benefits. With prostitution, facilitated by anonymity and economic exchange, men are able to simply offer resources (i.e., money) to obtain "just sex" (Salmon 2008). This allows men also (similar to the case of rape) to bypass the courtship often involved in relationship acquisition before being "allowed" sexual access to a woman.

Interestingly, women sex workers do not engage in prostitution for the same reasons men do (i.e., for "just sex"). Instead, they are largely engaged in prostitution for the economic and material rewards (i.e., the money). This is also predicted from an evolutionary perspective, whereby women show a deep resourcefulness for finding ways to obtain and secure economic and social resources for her and her children's well-being (Hrdy 1999).

Conclusion

Evolutionary forensic psychology provides an interdisciplinary theoretical explanation for many of the forensic-related issues facing society. From homicide to sexual harassment and from rape to infanticide, using an evolutionary perspective allows for rooting these deeply troubling social issues into a framework that explains why they exist and the specific contextual factors that may elicit their expression. Using the principles of evolution, evolutionary forensic psychology is primed to understand and explain why sex and age continue to be significant and reliable predictors of the commission of crime across the globe. Criminal activity is certainly socially disruptive and emotionally devastating, but its enactment does not only produce costs for the individuals committing these actions; they are also permeated with benefits, many of which are connected to the evolutionary expectation of enhancing reproductive success through resource acquisition, status accumulation, and mating. Understanding these benefits and the costs of criminal behavior may better allow us to tailor interventions toward reducing the prevalence and impact of criminal behavior on individuals and society as a whole.

Evolutionary Foundations of the Attachment System and Its Functions

Definition

The attachment system, as defined by John Bowlby, is a behavioral control system that continuously monitors proximity to caregivers. Bowlby argued that the attachment system has been retained as proximity to caregivers has been associated with increased chances of survival, and ultimately reproduction, in humans’ ancestral environments.

Introduction

Universally, human infants form strong bonds – attachments – to their caregivers. That is, children who have formed attachments seek to maintain proximity to their caregivers and protest separations by means of positive (e.g., smiling,

vocalizing) and aversive (e.g., crying, screaming) signaling behaviors and active behaviors such as approaching and following. Children's striving for proximity is particularly evident in situations that signal potential danger, in which children typically signal to and/or approach and cling to their caregivers. However, children also monitor their caregiver's whereabouts in absence of threat signals, using the caregiver(s) as a reference point, a "secure base," for exploration of the environment. John Bowlby, a psychoanalyst and child psychiatrist, sought to understand the phenomenon of attachment, which at the time was deemed secondary to other processes, such as psychical energies and the caregiver's ability to provide nourishment. Bowlby termed these theories, which he thought were unscientifically formulated, "secondary-drive theories" (see psychodynamic foundations).

Bowlby performed some initial research that pointed toward negative effects on children's development from prolonged separations from caregivers (Bowlby 1944) and conducted a report for the World Health Organization regarding the effects of separation (Bowlby 1951; see John Bowlby: Pioneer of Attachment Theory). To develop a scientifically based understanding of the nature of children's ties to their caregivers, Bowlby started a seminar group with participants from various scientific disciplines. This seminar group became important for Bowlby who came to draw on and integrate knowledge from evolutionary theory and ethology, cybernetics, and cognitive research. Bowlby became heavily influenced by evolutionary theory and ethology through the pioneering control theory ethologist Robert Hinde (e.g., Hinde 1970), who also became a close friend. Hinde was at the time shifting his own research interest toward mother-infant interactions in rhesus monkeys, and Bowlby noted that infant rhesus monkeys showed a pattern of behaviors in relation to their mothers that was highly similar to that shown by human infants (van der Horst et al. 2007). Bowlby realized the potential of explaining human attachment behaviors using evolutionary and ethological theory. Not only was ethology concerned with the development of close social bonds between animal offspring and their

parents, but it was also firmly anchored in the usage of empirically grounded methods such as naturalistic observations which appealed to Bowlby's scientific ideals. The evolutionary foundation of the attachment system and its function, as outlined by Bowlby, is discussed below.

Evolutionary and Ethological Foundations of Attachment Theory

Development of Behavioral Systems

Ultimately, Bowlby's starting point became evolutionary theory, following Darwin (1859) and the theory of natural selection. Indeed, Bowlby argued that attachment theory is "a direct descendant of the theory outlined by Darwin in *The Origins of Species*" (Bowlby 1997/1982, p. 172). Moreover, Bowlby felt that ethology was the best application of Darwin's theories to behavioral systems in animals and argued that humans, like all other species, should have become endowed with behavioral systems that once evolved have been retained because they have served an adaptive function in our ancestral species-typical environments. More specifically, individuals who became endowed with certain behavior systems had increased rates of survival and ultimately reproduction (see infant survival). Thus, the genes of these individuals must have been differentially passed on to future generations by these individuals having more progeny, and such behavioral systems therefore eventually became stable characteristics of a species. As argued by Bowlby, "...once gene survival is recognized as the true criterion in terms of which the function of instinctive behavior is measured; some old-standing problems evaporate" (Bowlby 1997/1982, p. 133).

Bowlby explicitly argued against teleological explanations, such that behavioral systems were caused by their outcomes so as to serve a specific purpose. For example, saying that birds are building nests to have somewhere to rear their young, and implying that this particular "need" causes the nest building, would be an example of a teleological statement according to Bowlby. As argued by Bowlby; "...because such a theory entails

supposing that the future determines the present through some form of ‘finalistic’ causation, it lies outside the realm of science” (Bowlby 1997/1982, p. 125). Bowlby therefore drew a strict line between cause and function. According to Bowlby, causes are those circumstances that activate and terminate a behavior system, whereas its function is related to the consequences that typically arise from the way the system is structured (cf. predictable outcome; see below). Needs, such as having somewhere to rear offspring, do not cause behavior systems per se; they constitute the selection pressure under which behavioral systems have evolved and have thus determined the functions they serve. Function, therefore, can only be ascribed afterwards, as an explanation for why a characteristic has become more common in a species. Some behavioral systems and their respective behaviors have just happened to be differentially functional as regards increasing rates of survival and have therefore been retained through the process of natural selection.

Predictable Outcomes and Functional Consequences of Behavioral Systems

Bowlby used the term predictable outcome to denote the species-typical functional consequence of the activation of a behavior system. As regards attachment Bowlby argued that proximity to caregivers is the predictable outcome of activation and protection from dangers its functional consequence. Indeed, the signaling behavior and active approach behavior that children show when the attachment system is triggered by internal (e.g., pain, illness) and external signals of threat (e.g., threatening external stimuli, separation from the caregiver) tend to result in proximity to caregivers (and thereby protection). Bowlby was however careful to differentiate between predictable outcome and functional consequence. In any given individual, the functional consequence (i.e., the species-typical predictable outcome) may only sometimes, or never, follow from the activation of a behavioral system. As argued by Bowlby, in any given individual, a behavioral system becomes active, reaches a more or less typical predictable outcome, and then becomes inactive, all without reference to the system’s function.

Bowlby exemplified this with infants’ sucking of dummies, which does not result in nutrition. As regards the attachment system, some children’s proximity-seeking behavior is met with rebuff/rejection (see “individual variations in attachment”) or even potentially harmful responses (see “disorganized attachment and reactive attachment disorder”). Bowlby therefore argued that understanding of any system’s function is impossible from studying any single individual; it necessitates studying a population of individuals. Whereas predictable outcome refer to the working of a system in a particular individual, functional consequence refers to a property in a population of individuals. However, for a population to survive, and hence for a behavior system to be retained, it is important that the predictable outcome is consonant with its functional consequence in a sufficient number of individuals. In the case of attachment, the predictable outcome of proximity to caregivers must have resulted in its functional consequence of protection in a sufficient number of individuals.

The Environment of Evolutionary Adaptedness and Development of Behavioral Systems

In tracing the function of behavioral systems, and the attachment system in particular, Bowlby argued that functions must be sought in the environment(s) in which humans have historically evolved, which have provided the pertinent selection pressures. With the words of Bowlby, “Just as Darwin found it impossible to understand the structure of an orchid flower until he knew what insects flourished and visited it. . . , so, it is held, it is impossible to understand man’s instinctive behavior until we know something of the environment in which it evolved” (Bowlby 1997/1982, p. 61). Bowlby termed this environment the “environment of evolutionary adaptedness” (EEA). This assumption and terminology was later picked up as an important guiding principle in evolutionary psychology (see Laland and Brown 2011; Tooby and Cosmides 1990). Bowlby argued that in our primeval environment, humans were living as nomads in small hunter-gatherer societies, in an environment comparable to that of other large

ground-living species of higher primates. A key characteristic of our ancestral environment, according to Bowlby, was a risk of falling prey to predators and other natural dangers. Thus, a behavioral system that helped increase and maintain proximity to caregiver(s) should have served an important function that increased the chances of survival. Human children are indeed born very vulnerable and thus dependent on their caregiver's support for a proportional amount of time largely unparalleled in other species. With the words of Bowlby, "Because immature organisms are usually very vulnerable they are commonly endowed with behavioral equipment that produces behaviors specifically likely to minimize risk, e.g. behavior that maintains proximity to a parent" (Bowlby 1997/1982, p. 143). Thus, Bowlby argued that proximity to caregivers is the predictable outcome of activation of the attachment system, as proximity to caregivers reduces the risk of falling victim to predators and other natural dangers. Hence, Bowlby argued for a narrow definition of the functional consequence of proximity, as opposed to alternative suggestions that proximity to caregivers may have increased chances of learning skills important for survival from caregivers (see infant survival).

Bowlby noted that human infants typically display a specific sequence of reactions following separations from their caregivers: protest, despair, and detachment. Protest, shown by aversive signaling behaviors, draws the attention of the caregivers and may prevent separation (i.e., maintain proximity). Evolutionarily, it can be argued that children left unattended in our ancestral EEA were more susceptible to predators and other dangers. During despair, which follows if a separation is prolonged, children's motor activity typically declines and they become more silent. Evolutionarily, this may have been an adaptive secondary strategy as excess movements and loud protests, when not in the proximity of the caregiver, may have increased the risk of injuries or drawn the attention of predators. During the final stage, detachment, which follows if the separation is not ended, infants gradually resume normal behavior and become more receptive toward other individuals. Bowlby argued that this may

have facilitated the formation of new attachment bonds (i.e., maintaining proximity to a new attachment figure). From an evolutionary perspective, this may be adaptive as new caregivers may be willing to provide the resources necessary for survival (Simpson and Belsky 2008). The various patterns of attachment that children develop, which primarily depend on the caregiver's pattern of responding to the child's signals (see individual variations in attachment), have also been described as different strategies to obtain as much proximity to the caregiver as possible (Main 1981; Main and Solomon 1986).

Bird Imprinting and Attachment Behavior in Other Primates

Bowlby drew heavily from all ethological research existing at the time. Indeed, it has been said that Bowlby was a psychoanalyst by trade but an ethologist at heart (Suomi 1995). Accordingly, Bowlby argued that insights into behavioral systems in humans may be gained from knowledge about the behavioral systems of other species and that our behavioral systems, although they may seem unique to us, should be seen as modifications of prototypes found in other species. With the words of Bowlby: "...we share anatomical and physiological features with lower species, and it would be odd were we not to share none of the behavioral features that go with them" (Bowlby 1997/1982, p. 7). Bowlby was particularly influenced by Konrad Lorenz (1963), Niko Tinbergen (1951/1963), and Harry Harlow (1958).

Bowlby regarded Lorenz's (1963) research regarding birds' imprinting as the first findings to seriously question the secondary-drive hypothesis. Bird offspring, who themselves had the ability to find food and thus were not reliant on their parents for nutrition, nonetheless formed strong bonds to and followed the parent wherever it went. Hence, Bowlby reasoned that proximity to the parent must have evolved due to it serving a function other than nourishment. Lorenz had originally argued that imprinting was unique to birds, that there was a critical phase early in development where imprinting had to occur, that imprinting was irreversible whence formed, and that

imprinting was fundamentally distinguished from other types of learning. However, research that followed subsequently revised these claims, for example, showing that imprinting is reversible and that sensitive periods are a more appropriate characterization than critical periods. Perhaps most importantly for Bowlby, the features of imprinting also seemed applicable to mammals to some degree. Indeed, the phenomenon of imprinting was descriptively similar to the two main characteristics of attachment: maintaining proximity to another animal and a specificity of the other animal (i.e., the caregiver[s]). Bowlby therefore accepted the phenomenon of imprinting in a generic sense, implying the development of a clear preference, which develops rather quickly and during a limited phase of life and that once formed remains relatively fixed. However, as acknowledged by Bowlby, drawing conclusions about behavior systems in humans from behavior systems in birds is problematic, since the phylogenetic lines of birds and mammals parted early in evolution.

Harlow's studies on rhesus monkeys (e.g., Harlow 1958) therefore became important for bridging the gap. Indeed, it has been argued that Bowlby tailored attachment theory to not only account for the behaviors shown by virtually all human infants but also those shown by our closest evolutionary relatives (Suomi 2008). Harlow performed multiple experiments with rhesus monkey infants and inanimate surrogate mothers, for example, comparing the importance of the surrogate mothers' ability to provide nourishment or closeness and warmth. In one of the experiments, Harlow used a steel-clad surrogate mother that was able to provide nourishment and one soft wool-clad surrogate mother that could not provide nourishment but that could provide closeness and warmth. Contrary to the secondary-drive theories, the young rhesus monkeys preferred the soft surrogate mother and only clung to the steel mother that could feed them when hungry. With the words of Bowlby, "All these experiments showed that 'contact comfort' led to attachment behavior whereas food did not" (Bowlby 1997/1982, p. 213). Interestingly, further experiments also

revealed that the infant rhesus monkeys preferred the soft wool-clad surrogate mother even when it hurt and frightened the infant monkeys (e.g., using a buzzer that blasted compressed air through the nostrils). In fact, the rhesus monkey infants even clung harder to the surrogate mother then. Although this latter finding may seem counter-intuitive, Bowlby argued that it was logical from an attachment perspective. If the function of the attachment behavioral system is seeking and maintaining proximity to caregiver(s), particularly in situations signaling potential danger, and they were attached to the surrogate mother, they would "instinctually" seek proximity when frightened.

In this vein, Bowlby referred to attachment behaviors as "instinctual" in a descriptive sense, pertaining to behaviors that show great regularities within a species (following a similar and predictable pattern in almost all members), that is not just a simple response to a stimulus but a sequence of behaviors that have usual outcomes that are of survival value and that typically develop even when most opportunities for learning are absent. In the case of attachment, Bowlby noted that "attachment of young to parents are found in almost all members of the human race and seem best considered as expressions of some common plan and, since they are of obvious survival value, as instances of instinctive behavior" (Bowlby 1997/1982, p. 39). Bowlby argued that the similarities between humans and other animals were likely due to convergent evolution since many species have shared the same evolutionary environment, containing a risk of falling prey to predators.

Bowlby reviewed a number of observations of human infants indicating that attachment behavior in humans resembles those of other mammals; "...the development of attachment behavior in human infants, though much slower, is of a piece with that seen in non-human mammals. Much evidence supports that conclusion and none contradicts it" (Bowlby 1997/1982, p. 222). For example, once attached, infants prefer the attachment figure to other persons, typically persisting even in the face of separations. As for other mammals, human infants are also born with the

capacity to cling. Human infants also show a narrowing of responsivity to objects, which over development (though with a slower pace) becomes more directed toward a few objects (i.e., caregivers). Human infants also show a marked bias toward responding to particular stimuli (such as human faces), and the more experience with a particular person, the stronger the preference. Bowlby also argued that the early development of attachment in human infants, which typically forms during the first year, could be taken as an indication that there may also be a sensitive period for attachment in humans.

Interestingly, attachment theory, as outlined by Bowlby, has subsequently been successfully applied to ethological research on rhesus monkeys. As reviewed by Suomi (2008), infant rhesus monkeys show some patterns of relationships with their mothers that parallel the attachment patterns found in human infants, which as for humans depend on the caregiver's pattern of responding. Bowlby's and Ainsworth's "secure base" phenomenon has also been shown to be applicable to infant rhesus monkeys, and as for humans, an inability to use the parent as a secure base from which to explore is related to maladaptive development in rhesus monkeys (see "effects of attachment quality and organization").

Nature vs. Nurture and Behavioral Systems

Bowlby sought to avoid getting into a debate about whether the attachment behavioral system was innate or learned. Drawing on Hinde (1959), he thought of behavioral systems on a continuum of more or less "environmentally stable or instable," with environmental effects and learning most pertinent to more instable systems. Bowlby also argued that what is inherited is not an instinct per se but a potential to develop certain sorts of behavioral systems and that "the forms . . . differ in some measure according to the particular environment in which development takes place" (Bowlby 1997/1982, p. 46). Bowlby argued that the human attachment system is a moderately stable system, which may stem from the fact that behavior typically described as instinctual tends to be stable as long as the environment remains in the range of

that in which a species typically lives. Importantly, in the case of attachment, the species-typical environment generally includes caregivers responding to children's signals, thus rendering the phenomenon of attachment a relatively stable characteristic (but see "disorganized attachment and reactive attachment disorder" for detrimental effects following severe social deprivation). Indeed, Bowlby argued that the attachment system is complemented by a caregiving system in adults, which makes caregivers responsive to their children's signals. Following inclusive fitness theory, Bowlby argued that the caregiving system has developed as the adult's genes are only passed on to future generations to the extent that their offspring survives to reproduce. Thus, child attachment develops through a collaborative and synchronized process, with children socially biased and prepared to bond with their caregivers by drawing their attention through signaling behaviors and caregivers biased to respond to children's signals (Simpson and Belsky 2008). The development of attachment seen in almost all children has been termed the universality principle of attachment theory (van IJzendoorn and Sagi 1999).

Although stable in one sense, the attachment system is also moderately labile. Although labile systems typically have a disadvantage of taking time to mature and become functional, Bowlby argued that the advantage of such systems, which are open to learning, is that they permit modifications to suit the environment at hand. However, no systems can be suited to work in all environments, and if a system gets programmed for a particular environment, it may not work well in different environments. Openness to learning is, for example, seen in the relation between quality of caregiving (e.g., sensitivity) that children receive and the different organization of attachment behaviors (i.e., quality of attachment) that they develop (see "individual variations in attachment"). Thus, a consequence of the instability of the system is also that atypical environments can make the attachment system programmed in such a way that a child becomes at risk for problems in other environments (see "effects of attachment quality and organization").

A Control Systems Approach to Behavior Systems

Inspired by Hinde, who applied control theory in ethology, Bowlby also drew from control systems theory for understanding the basic structure of the attachment behavioral system. As outlined by Bowlby, any system serves a particular function (i.e., has an instruction/plan), a goal that it is preprogrammed to achieve. Bowlby argued that these instructions have reached us through natural selection and termed these the “set goals” of the systems, which he argued can be either for time-limited events or ongoing conditions. Bowlby argued that the set goal of the attachment system is continuous, as the task of the attachment behavioral system pertains to “control” of an ongoing relationship (i.e., continuous maintenance of spatial relations in relation to certain objects over time).

Apart from having a set goal, feedback is another important part of complex behavioral control systems. By feedback, and using machines (e.g., thermostats, missiles) as a metaphor, Bowlby referred to processes “... whereby the actual effects of performance are continuously reported back to a central regulating apparatus whereby they are compared with whatever instruction the machine was given; the machine’s further action is then determined by the result of this comparison and the effects of its performance are thus brought ever closer to the initial instruction” (Bowlby 1997/1982, p. 42). The degree of activation of the attachment system therefore varies depending on sensory input from internal or external sources, with activating signals (internal/external), those that signal possible danger, and terminating signals, those signals (internal/external) indicating that there is no more cause for alarm.

Bowlby argued that behavioral systems can be more or less complex, depending on whether they are organized to take feedback regarding ongoing performance into account in order to achieve their predetermined outcome (i.e., their evolved function). Fixed action patterns, which whence they are triggered by a stimulus tend to reflexively run their course with little account of ongoing feedback, exemplify simple behavioral systems. Such

patterns are often organized like chains of behaviors with actions of certain behavior systems in a specific order. The effect produced by one behavior system terminates the actions of that system and triggers the actions of the next system. Bowlby exemplified this notion with the collection of honey by bees, wherein bees first react to a certain color of a flower that triggers approach behavior, when getting closer to the flower reacting to the smell of the flower, etc. These behaviors are triggered in a certain order, and no step can be skipped. Although such systems can be intricate and important, their performance fails if the action of one link miscarries, as in the saying that no chain is stronger than its weakest link (Bowlby 1997/1982).

Bowlby used the term “goal corrected” for more complex systems, such as the attachment system, which are structured by means of feedback. That is, goal-corrected systems continuously monitor deviations between the set goal and current performance. However, Bowlby argued that the special characteristic of goal-corrected systems is the process by which they reach their set goal. Goal-corrected systems are typically not stereotyped and organized in chains, but rather by means of plans in plan hierarchies (cf. executive functions). Here Bowlby drew from Tinbergen (1951) and Miller et al. (1960) to denote that complex goal-corrected systems can make use of varying behaviors depending on the situational constraints and perform behaviors in different orders. Following activation of the attachment system, a child can, for example, cry in one situation and approach and cling to the caregiver in another. The advantage of such systems is thus that the predictable outcome can be achieved even though circumstances vary substantially. Bowlby argued that many behavioral systems of humans, as compared to other species, are complex and goal corrected, although we are endowed with a mix between simple and complex systems.

Bowlby further argued for a maturational developmental perspective on goal-corrected behavioral control systems such as the attachment system. The attachment behavioral control system, he argued, is not a functional goal-corrected

system at birth but develops into one with maturation. The reason for this is that the operation of goal-directed systems is mediated by various other systems and thus dependent on their development. Therefore, behavioral control systems tend to be organized as simple chains in infancy and become more goal corrected over time as more simple behavior systems become integrated under higher-order systems. For example, the reliance on sensory feedback makes the attachment system dependent on the development of the sensory organs. Behaviors also need to be oriented, and effector equipment such as locomotor ability is therefore important for goal-corrected behavior. Indeed, a child who has acquired the ability to crawl and walk is much more able to independently regulate proximity to the caregiver in a goal-directed manner.

Organisms also need to be able to organize sensory input into representations of the world, and goal-corrected attachment behavior therefore depends also on cognitive development. Bowlby used the term “internal working models” (IWMs), adapted from early artificial intelligence theorizing by Young (1964), to denote such cognitive representations of the environment: “The use to which a model in the brain is put is to transmit, store and manipulate information that helps in making predictions as to how what is here termed set-goals can be achieved” (Bowlby 1997/1982, p. 80). Bowlby thus argued, as do many current-day cognitive psychologists, that the brain is a prediction apparatus. Part of our immense adaptability and complexity is that we can make small-scale experiments based on our IWMs, to guide our behavior in various future situations that are, to varying degrees, similar to ones already encountered. Bowlby argued that we necessarily construct one organismic model (a model of ourselves and our abilities) and one environmental model (a model of others, including what to expect from others). These models, which are often referred to as models of self and others in attachment theory, are thought to be complementary. In order to function adaptively and not become too rigid, these models must be open to learning so that they can be continuously updated. Drawing from Piaget (1955), Bowlby argued that

we typically make small corrections to our models, and the IWMs become stable due to information being assimilated into the current models. However, given sufficiently strong new input, substantial change occurs through a process of accommodation.

Attachment Theory and Current Evolutionary Perspectives

Inclusive fitness theory may be regarded as the current superordinate theory of evolution (Simpson and Belsky 2008), encompassing Darwin’s notion of fitness according to one’s own reproduction and Hamilton’s (1964) notion of kin selection (i.e., that reproductive fitness also includes reproduction by biological relatives). Theories addressing specific adaptive problems that humans have faced are placed one level below and called “middle-level theories.” Attachment theory is today generally seen as one such middle-level theory. The principles put forth by middle-level theories are in turn regarded as one further level down, in the case of attachment theory pertaining to principles regarding species-typical development (development of an attachment bond) and development of predictable patterns of individual differences. Attachment is conceivably one of the first theories to acknowledge the need to describe both normative (or species-typical) development and individual variations.

It has however been argued that Bowlby focused too much on the survival function of attachment behaviors and not sufficiently addressed its possible role for differential reproduction (Simpson and Belsky 2008). For reproductive fitness, it is argued that not only must one survive into reproductive age, one must also leave progeny which in turn reaches reproductive age and leaves progeny (and so on). Thus, some attachment researchers are now exploring if childhood variations in attachment are related to different reproductive strategies in adulthood (e.g., Belsky 2007; see also “attachment in adulthood”). Relatedly, attachment research has been critiqued for advocating a notion of one

solitary human EEA, with the secure attachment pattern advocated as a “species-typical”/primary pattern and the insecure patterns as deviations/secondary strategies. In contrast, it has been argued that there were multiple EEAs and that the different childhood and adult attachment patterns all represent different adaptive tactics designed for improving reproductive fitness in their respective EEAs. Moreover, it has been argued that Bowlby’s attachment theory “equates” the interests of parents and offspring and does not acknowledge differences in reproductive interests between parents and children, as, for example, captured in Triver’s (1974) -parent-offspring conflict theory (see also Bowlby 1997/1982). According to parent-offspring conflict theory, parental investment in a particular child should depend on both benefits and costs of the investment. Theories following this line of reasoning argue that variations in parental investment and sensitivity, and subsequently variations in attachment, should partly stem from cost-benefit trade-offs due to, for example, attributes of the parent and the child, the family (e.g., presence of siblings), and the local environment. Lastly, attachment theory has been critiqued for putting too much emphasis on mothers as the principal attachment figures. For example, cooperative breeding theory (Hrdy 2005) emphasizes that cooperative parenting, involving other adults and older siblings (alloparents), has likely been the norm throughout our ancestral history.

Conclusion

In formulating attachment theory, Bowlby drew on Darwin’s theory of natural selection and ethological theory and research, including imprinting and control systems theory as applied in ethology. The human attachment system, similarly to other animals, is argued to constitute a behavioral control system that has been retained because it served an adaptive function in our ancestral environments. Specifically, Bowlby argued that the set goal of the attachment system is maintaining a certain degree of proximity to

caregivers and that the predictable outcome of activation of the attachment system is increased proximity to caregivers, which has served an evolutionary function of protection against predators and other natural dangers. Lastly, it has been argued that the attachment system develops into a complex, goal-corrected system that continuously uses feedback to monitor deviations between its set goal and its performance and that this system is moderately labile and open to learning.

Evolutionary Hierarchy of Needs

Matthew J. Scott

University, Tempe, AZ, USA

Synonyms

[Fundamental motives](#); [Fundamental social motives](#)

Definition

A framework of universal human needs that have been naturally selected because they promote relatively higher reproductive fitness.

Introduction

Abraham Maslow's (1943) hierarchy of human needs continues to enjoy fame in the popular consciousness. Briefly, Maslow posited that humans have a universal suite of basic needs that appear in sequence as each need is met. According to this framework, fulfilling immediate physical needs frees attention to fulfill security needs,

which leads to pursuing social needs for love and belonging, followed by ego needs for power and prestige, and finally the need to self-actualize by pursuing one's highest potential. Recent work taking an evolutionary approach to motivation "renovated" Maslow's pyramid (Kenrick et al. 2010a; see Fig. 1). Current evolutionary theory suggests that, inasmuch as these needs are universal, they ultimately serve to promote reproductive fitness. Viewed this way, self-actualization is still a lofty goal, but the ultimate function of it or any other motivated pursuit is to satisfy evolved needs. Furthermore, evolutionary theory suggests that needs would not emerge in discrete stages but would come online throughout the life span, interplaying with life stage and environment.

Evolved Needs

Humans are believed to possess evolved psychological mechanisms that solve recurrent challenges to reproductive fitness. The renovated pyramid of fundamental motives is comprised of those universal drives, which, when satisfied, can help humans increase their fitness (Kenrick et al. 2010a; see Fig. 1; Kenrick et al. 2010b; Schaller et al. 2017) (Kenrick et al. 2010a, b; Schaller et al. 2017). According to the fundamental social motives model, the drives to protect oneself from danger, avoid diseases, build a social network,

acquire social status, find a mate, keep that mate, and care for kin all help to promote fitness. For example, a drive to avoid diseases might help to promote fitness by motivating individuals to steer clear of visibly infected others.

The Sequence of Needs Within the Hierarchy

Unlike Maslow's model, individual fundamental motives are not part of a strict gatekeeping order by which one graduates to a new level of motivation and forgets the previous one. Instead, lower goals make way for higher goals but also remain online in the service of reproductive fitness. For example, we are just as repulsed by rotten foods after having children as we were before. Lower motives do not necessarily atrophy when higher motives are satisfied. Also note here, however, that some higher goals cannot be met without first achieving lower ones (e.g., mating and caring for offspring).

Thus, different goals can become salient in different situations (Morse et al. 2015). Any number of fitness-relevant stimuli can activate a fundamental motive to selectively focus attention and energy toward mitigating a current threat or taking advantage of a current opportunity (Kenrick and Krebs 2018). For example, when a self-protection motive is activated, memory for potentially threatening male faces improves even

Evolutionary Hierarchy of Needs, Fig. 1 Maslow's (1943) pyramid of needs (left) and Kenrick et al.'s (2010a) revised pyramid of needs (right)

though no additional attention is observably paid (Becker et al. 2010).

Individual Differences and Changes in Focus over the Lifespan

The Fundamental Social Motives Inventory (FSMI; Neel et al. 2016) is a reliable measure of evolved needs which confirms that individual differences in each of these social domains predict unique variance in cognition and behavior. For example, individuals higher in the self-protection motive are more likely to believe the world is a dangerous place and to have taken steps toward increased safety in the past year (e.g., improved home security, self-defense classes).

An evolved hierarchy of needs likely promotes individual fitness in different ways depending on life history variables and ecological conditions, meaning that individuals vary in which motives are chronically salient. For example, we might expect that status motives are more salient for men – and especially single men – because women prefer high-status males (Buss 1989). When ecological conditions include resource scarcity and concomitant violence, self-protection motives are more likely to be chronically active. Recent evidence suggests that evolved motives do vary in response to life history variables. Mate-seeking motivation is higher among men and decreases with age, whereas kin care motivation is higher among parents and especially those with young children (Neel et al. 2016).

What to Do with Self-Actualization?

Self-actualization is a state wherein an individual has all basic needs met and is pursuing his or her highest potential (Maslow 1943). Individuals who have reached their fullest potential are said to be self-actualized. Unlike Maslow's pyramid of needs, an evolutionary hierarchy of needs does not count self-actualization as the apex of human motivation but instead as a vehicle for promoting reproductive fitness. For example, one might self-actualize by becoming an excellent violinist, but there is no

reason to expect that evolution has programmed humans to master musical instruments. Rather, evolution has programmed humans to seek optimal reproductive fitness through a variety of available means. An evolutionary hierarchy of needs posits that any self-actualizing activity is undertaken ultimately to promote reproductive fitness.

Humans pursue fitness-relevant goals, as doing so may have reliably increased reproductive fitness (Symons 1992; Tooby and Cosmides 1992). Likewise, activities that make us feel good are thought to do so because they signal progress toward some fitness-relevant goal(s). To the extent that self-actualization is a universal need and/or feels good, this suggests that it may signal progress toward adaptive ends. Indeed, research suggests that creative pursuits (self-actualizing behaviors) are one avenue toward gaining social status and attracting mates (Griskevicius, Cialdini, & Kenrick 2006; Miller 2000), suggesting that self-actualizing activities may be associated with fitness-relevant goals. Krems et al. (2017) found that participants strongly associated their own self-actualizing activities (e.g., “working on my PhD in biology”) with pursuing status (and affiliation). Recent experimental work (Scott and Cohen 2019) further supports such theorizing that well-being tracks progress toward fundamental social goals (Krems et al. 2017; Kenrick and Krems 2018): Participants randomly assigned to write about fully accomplishing their kin care and mating goals felt increased purpose in life, as did those writing about status achievements. Taken together, the evidence suggests that self-actualization is associated with – and may ultimately serve to promote – reproductive fitness.

Conclusion

From an evolutionary perspective, any universal hierarchy of needs must be associated with reproductive success.

Definition

Evolutionary medicine is a transdisciplinary field of study aimed at applying evolutionary concepts and thinking to our understanding of medicine.

Introduction

Unlike the traditional approach to medicine which is aimed at identifying and treating the proximate causes (i.e., symptoms) of disease, an evolutionary medicine approach is focused on identifying the evolutionary origins (ultimate cause) of a disease and to use this to help inform medical

practice (Williams and Nesse 1991; Trevathan 2010; Ruhli and Henneberg 2013). Evidence in support of evolutionary medicine is provided by observers working in various fields, including cognitive science, anthropology, demography, biochemistry and molecular biology, and genetics. Evolutionary medicine thus offers a broader and more holistic perspective to medicine. The significance of using an evolutionary approach to medicine is highlighted by the tremendous insight gained from our understanding of antibiotic resistance (Davies and Davies 2010) and the rise in recent viral or bacterial outbreaks (e.g., Ebola, Measles, COVID-19). Interest in evolutionary medicine has grown exponentially (Alcock 2012) with this field contributing significantly toward our understanding of important topics in human health including immune function (Cooper and Herrin 2010; Litman and Cooper 2007), aging (Stearns et al. 2000; Stearns 1989), infectious disease (Ewald 1994; Schmid Hempel 2011), reproductive health (Trevathan 2011), behavioral and mental disorders (Keller and Nesse 2006; Nesse 1999), inflammation (Straub 2012), diet (Chakravarthy and Booth 2004), and cancer (Merlo et al. 2006).

History

Neese and Williams (Williams and Nesse 1991) are credited with bringing about a resurgence of interest in the field of evolutionary medicine through their now classic articulation of the key concepts covered by a “Darwinian” approach. However, the field of evolutionary medicine has a much longer and often forgotten history dating back to some of the earliest champions of the comparative approach (Trevathan et al. 2008). Aside from the seminal work of Charles Darwin, to whom we owe the foundations of our current understanding of evolution, one of the earliest proponents of evolutionary medicine was in fact Charles’s grandfather, Erasmus Darwin. Erasmus was one of the first physicians to think about the impact of nature on humans and published a taxonomic catalog of known diseases of his day, along with their causes and treatments (Darwin 1794–1796). In 1926, physician Dudley J. Morton expounded on Darwin’s views and stated that

diseases should be viewed through the lens of human variation and adaptation and that clinicians should aim to understand the evolutionary basis of adaptation to disease (Morton 1926). While these early calls to action linking evolution to medicine were somewhat forgotten in the early part of the twentieth century, what emerged from them was a growing interest in understanding human adaptations to particular environments and its impact on the underlying anatomy and physiology. By the middle of the twentieth century, this emerging research area was further enhanced by studies of sickle cell disease in various populations, demonstrating that variation in human hemoglobin structure was associated with immunity to the malaria parasite (Allison 1953, 1954; Barnicot, Ikin, and Mourant 1954). Furthermore, the impact of humans on the environment and our role in disease propagation was highlighted by further studies emerging from this field, highlighting the influence of human agriculture on the breeding behavior and distribution of the malarial parasite (Livingston 1958). In the later part of the twentieth century, questions in evolutionary medicine have extended upon these earlier themes to identify diseases of modernity (e.g., type 2 diabetes, hypertension, addiction) and their evolutionary origins as well as the role of human activities and industrialization in shaping disease progression (Trevathan 2010). Some of these topics include the appearance of novel metabolic processes such as lactose tolerance (Matthews et al. 2005), the genetic variations in the abilities of humans to process alcohol (Jornvall 1994), changes in the human skeleton (Schwidetsky 1962; Ruff 2002), changes in human body weight and height (Katmarzky and Leonard 1998), and changes in the size and number of human teeth (Brace et al. 1987). These and other microevolutionary changes to the human body likely resulted from environmental changes resulting from modern living (Ruhli and Henneberg 2013).

Fundamentals of Evolutionary Medicine

Before outlining some of the core principles of evolutionary medicine, it is important to remember the basic assumptions of Darwinian evolution and one of the auxiliary theories often used in

evolutionary medicine. In order for a feature to be considered Darwinian in nature, (1) the feature must exhibit variability in phenotype, (2) this variability must be heritable (i.e., transmitted from parents to offspring), and (3) the feature must exhibit selective fitness (i.e., impact species reproduction and/or survival to reproductive age) (Boyd and Silk 2009). The auxiliary theory often used in evolutionary medicine is that of life history theory which recognizes that the growth, maintenance, and reproduction of the organism is determined by the differential allocation of energy budgets which are themselves influenced by Darwinian processes (Stearns 1989). While the scope of evolutionary medicine covers all known areas of human disease, Neese and Williams (Williams and Nesse 1991) originally described five major categories of evolutionary explanation to which “Darwinian medicine” could be applied. Recently, using an expert consensus approach, the components of evolutionary medicine have been expanded to include a more extensive list of core principles, aimed not only at focusing the teaching of evolutionary medicine but also at guiding ongoing research in this field (Grunspan et al. 2018). Below, we briefly outline some of these core principles agreed upon by experts in the field.

Proximate vs Ultimate Causes and Host Defenses vs Pathogen Offences

One of the core principles of evolutionary medicine is distinguishing between the mechanistic (proximate) and evolutionary (ultimate) explanations for a disease (Grunspan et al. 2018). The difference between these two explanations is often conveyed as the dichotomy between the questions “what is the disease” or “how does it form” versus the question of “why the disease exists in the first place” (Spoceter and Strkalj 2007). Both mechanistic and evolutionary explanations are important to completing our understanding of the human body and disease vulnerability (Williams and Nesse 1991).

Building from this approach, it is also important to recognize that many signs and symptoms of disease may in fact form part of the body’s natural defense mechanism (Ewald 1980). From this perspective the protective nature of host

defenses, which include among other signs nausea, vomiting, pain, fatigue, and diarrhea, are distinguished from that of pathogen offenses (Williams and Nesse 1991). The challenge for the clinician is thus knowing when to interfere with these inherent host defenses as the cost of intervention while alleviating discomfort for the patient may result in the promotion of pathogen transmission and offenses. For example, studies of Shigellosis infection have demonstrated that diarrhea in these cases is in fact a host defense mechanism used by the body to reduce the contact time between the pathogen and the intestinal lining (DuPont and Hornick 1973). Thus, treatments which decrease the frequency and number of bowel movements (e.g., Lomotil therapy) are contraindicated in Shigellosis infection as they result in extended illness in the patient and are likely to contribute to the patient becoming a carrier of this infection (DuPont and Hornick 1973).

To think of it another way, one can consider this example as highlighting the importance of distinguishing between the immediate impact of a disease which is driven by the host defense response and its later impact which forms part of the pathogen offense. For example, a clinician might consider a fever as a (proximate) cause of an infection and in most cases would seek to treat this fever with fever-reducing drugs to spare the patient the immediate discomfort associated with the disease. However, several studies have shown that fever is a host defense mechanism and benefits the organism by decreasing viral replication rates in many pathogens while increasing the speed of immune reactions (Kluger 1979; Kluger et al. 1996). Thus, from an evolutionary medicine perspective, the reflex like tendency to administer fever-reducing drugs in most mild cases of fever is counterproductive as it diminishes the body’s natural ability to combat infection (Kluger and Rothenburg 1979). It is, however, important to note that an evolutionary medicine perspective does not advocate that fever-reducing drugs should not be used at all as there are particular cases as in a high fever where the impacts on the patient might exceed the limits of the immune response and thus intervention is necessary

(Trevathan et al. 2008). This is certainly the case for certain pathogens which are known to increase their reproductive fitness in response to fever (Ewald 1994). Another example of a host defense is the acute phase response, which results in a series of complex innate reactions shortly after tissue injury. As part of this defense mechanisms, there is the release of inflammatory cytokines (such as interleukin 6, tumor necrosis factor alpha, and interleukin 1 beta) which mediate the upregulation of acute phase protein, an important component of this systemic defense response, as well as several clinical signs which include fever, listlessness, and loss of appetite (Smith et al. 2013). The fact that these cytokines are found across vertebrate species suggests that the acute phase response is a universal defense mechanism shared by this group (Spocter and Strkalj 2007) and that the associated subcomponents to the response are likely to confer added defense to the organism (Weinberg 1984; Kluger and Rothenburg 1979; Hart 1985).

Sexual Selection and Reproductive Fitness

The scope of evolutionary medicine has grown to include the consideration of several important evolutionary processes. Among this wide range of processes, most experts in the field agree that this includes the classic Darwinian process of natural selection but also the consideration of genetic drift, mutation, migration, and non-random mating, all of which are important for our understanding of disease (Grunspan et al. 2018). In addition, the influence of sexual selection and reproductive success are also considered important concepts in understanding the origins of disease. For instance, the reproductive fitness of the organism could be favored by natural selection at the expense of health and longevity or could similarly decrease in response to other factors as argued for humans (e.g., Westendorp and Kirkwood 1998). In addition, the influence of sexual selection might also differentially impact health risks and outcomes in males and females (e.g., Janicke et al. 2016). Sexual selection is known to have a significant impact on the epidemiology of sexually transmitted diseases (STDs) (Janicke and Morrow 2019). Stronger

sexual selection in males results in males investing relatively more resources into mate acquisition at the expense of their own health and contributing toward riskier behavior in males (Zuk 2009).

Constraints, Trade-Offs, and Life History Theory

Several constraints might also prevent or inhibit the ability of natural selection to optimally shape human health and thus serve as an additional mechanism by which human susceptibility to disease might have evolved. These limits on natural selection include developmental, architectural, metabolic, or phylogenetic constraints (Spocter 2009) as well as trade-offs resulting from pleiotropy and mutations (Williams and Nesse 1991). For instance, one example of an architectural constraint known to have several clinical implications is the constraining influence of evolving bipedalism (Trevathan 2011). Humans are the only habitual mammalian biped, and those adaptations which make us uniquely suited to this form of locomotion have also made us susceptible to the occurrence of a range of clinical conditions including lower back pain and complications arising during childbirth (Spocter and Strkalj 2007). Furthermore, the evolution of bipedalism has also imposed constraints which have an impact on prenatal brain growth within the skull as the adult female is challenged with passing a relatively large head of a child through the relatively narrow pelvic outlet (Trevathan 2011).

Trade-offs in evolutionary medicine refer to the existence of linked changes between traits such that an evolutionary change increasing the fitness of one trait results in a decrease in fitness to another trait (Trevathan et al. 2008). In Neese and William (1991) articulation of Darwinian medicine, trade-offs were considered central to explaining disease vulnerability in evolutionary medicine and are intimately related to life history theory (Stearns 1989). Life history traits are shaped by natural selection and include traits such as the age of menarche and rate of senescence both of which have implications for human health and disease (Stearns 1989). In brief, one may understand the organizing principles of life

history theory as stressing that there is only a finite amount of energy available for an organism's growth, maintenance, and reproduction (Stearns 1989). Thus, the allocation of energy budgets to either corresponding life stages (e.g., gestation, weaning, lifespan) or growth within body components (e.g., body growth versus brain growth) requires trade-offs between components. For instance, energy spent on child rearing to maturity comes at a cost to energy that could have been used for reproduction, and in a similar way, energy spent on evolving a large brain (a metabolically expensive tissue) comes at the cost to free energy that might have been used for other organ systems such as the gut Aiello and Wheeler 1995).

Multiple Levels of Selection

Human vulnerability to disease may also result from the conflicting/opposing force of selection acting at different (or multiple) levels of organization (e.g., at the level of the molecule, gene, cell, organism, kin, or population) (Williams and Nesse 1991). Prime examples of this include genetic conflicts and somatic selection in cancer. For example, the differential interests of competing genes (or gene networks) in the human immune response could result in a myriad of genetic conflicts as the organism mounts a defense against an invading pathogen (Levin and Bull 1994). This conflict is a result of the complex and tiered arrangement of the host's defenses (Spocker and Strakalj 2007). Thus, understanding these complex interactions requires considering the differential impacts of selection at each level. Some postulate that sexual reproduction exists primarily to increase variability through rapid genetic change in response to the competing influence of pathogens (Hamilton et al. 1990). Similarly, it is argued that a genetic conflict between male and female gametes is responsible for the vast amount of sperm required for fertilization and the complexity of the female reproductive tract (Wedekind 1994).

Coevolution

Evolutionary medicine is also concerned with the influence of coevolution in driving health and

disease. Some examples include the establishment of an evolutionary arms race between a host and a pathogen (Ewald 1980), the establishment of symbiotic relationships such as those seen in the human gut microbiome (Williams and Nesse 1991), and the coevolutionary competition between bacteria resulting in antibiotic production (Davies and Davies 2010).

The effect of pathogens on the human body and their differing patterns of virulence (i.e., severity) have been the subject of much discussion in evolutionary medicine (e.g., Ewald 1980, 1988, and 1994). Society has become increasingly aware of differences in virulence between recent pathogenic threats (e.g., SARS-CoV2 versus Influenza A virus) and the importance of vaccination efforts and personal hygiene practices to ward off epidemic or pandemic spread (Ehret 2003). Some have argued quite cogently that the development of vaccines is an area in modern medicine which could benefit most strikingly if an evolutionary perspective is adopted (Read et al. 1999). Earlier arguments looking at the virulence of pathogens had supported the view that pathogens will naturally evolve toward less virulent states, a so-called equilibrium state, striking a balance between host survivability, transmission, and virulence (Levin and Svanborg-Eden 1990). Subsequent studies have shown that the concept of an equilibrium state falls short of describing all potential pathogen-host interactions and a richer view of virulence dynamics has emerged (Levin and Pimentel 1981; Frank 1996; Ebert 1999; Ebert and Bull 2003). Ewald (1980) has shown that the influence of "selfish gene" mutations in benign pathogens may still result in an increase in virulence provided that the rate of pathogen replication and transmission is increased. From an evolutionary perspective, transmission and replication of the pathogens genetic material is the most important consideration, not the state of its host, and thus host maintenance only becomes a consideration in cases where transmission is slow (Ewald 1980).

A further consideration in the evolution of virulence has been observation that some pathogens are able to effect host behavior to enhance transmission and that these pathogens tend to

progress toward greater states of virulence (Ewald 1988, 1994). While there are several striking examples of dramatic behavioral changes in hosts favoring pathogen transmission, such as the increased aggression and diminished fearlessness observed in hosts infected with rabies (Jackson 2016) or *Toxoplasma* (Berdy et al. 2000) and parasitic flukes (Wickler 1976), it is important to keep in mind that other more subtle changes in behavior may also help facilitate pathogen transmission. For example, while speculative, one might postulate that the relatively late onset of symptoms and the differential mortality in younger individuals as observed in the recent SARS-CoV2 pandemic might serve to enhance pathogen transmission, suggesting that this virus might continue to evolve toward increased virulence, impacting decisions on vaccine development. Mathematical modelling looking at the evolution of pathogen virulence has shown that vaccines that prevent infection may limit the virulence of the pathogen. However, those vaccines that only limit antitoxin immunity lead to increased prevalence and virulence (Gandon et al. 2001). In this regard, Read and colleagues (1991) have argued that rather than pursue the development of vaccines aimed at eliminating all forms/strains of a given virus, a more prudent and evolutionary informed approach would be to develop vaccines only against the most virulent strains of a virus, thus using mild forms of the virus as a means of conferring immunity. This approach is akin to that used in young children, where the child is infected with a mild strain of the virus through vaccination and from which subsequent immunity for all strains (including the more virulent ones) usually develops (Trevathan et al. 2008). Some argue that maintaining a coexistence with mild pathogenic strains is a more sustainable approach to vaccination, as a complete lack of exposure to a virus may leave a large sector of the population at risk to more virulent forms of a virus (Trevathan et al. 2008). It goes without saying that an awareness of host-pathogen interactions as viewed through the lens of evolutionary medicine is also critical to the way we address current or future healthcare crises both at the frontline as medical practitioners and biomedical

scientists but also as a global community, mindful of how our actions (or inaction) could promote pathogen transmission.

Evolutionary Mismatch/Adaptations to Novel Environments

For practitioners of evolutionary medicine, one particularly important source of disease is that which one might call “diseases of modernity.” These ailments, described as maladaptations, include diseases such as obesity, hypertension, type 2 diabetes, and back pain. It is hypothesized that these ailments arose as a result of a mismatch between the environments in which the human body evolved and that of our modern lifestyles to which our bodies have adapted to (Eaton et al. 1988; Eaton and Eaton 1991). Central to this hypothesis is the idea of an environment of evolutionary adaptiveness (i.e., an environment to which our bodies are most optimally adapted) (Irons 1998). Subsequent scientific discourse has seen the expansion of this idea away from the incorrect assumption that humans are optimally adapted to a single environment (e.g., a Paleolithic environment as initially proposed by Williams and Nesse 1991) and the acknowledgment that this mismatch may also result from migration between stable environments (Grunspan et al. 2018; Gluckman et al. 2016). The underlying principle is that there is a dichotomy between “past” and “present” such that our bodies (and minds) have not had enough time to adapt to our modern environments (Sharma 1998). For instance, one might consider obesity and its accompanying sequelae of hypertension and atherosclerosis as one example of a disease resulting from such an environmental mismatch. In comparison to Paleolithic communities, modern humans consume large amounts of sugars, salts, and fats (Eaton and Eaton 1991; Eaton et al. 1996; Nesse and Williams 1999), all of which were scarce and highly prized in Paleolithic communities but are relatively abundant in modern environments. Our brains, however, still perceive and process these stimuli as if we are in the Paleolithic, driving us toward acquiring larger quantities of these components to the detriment of our own health and exasperated by the reduction in

human activity levels. Another example of this type of maladaptation is that of human drug dependency (Lende 2008), with comparative genomic studies indicating an interesting overlap in genes involved in addiction propensity and human self-domestication (Calvey 2019). In addition, human sleep disorders may also result from our modern environments. In primate evolution, we observe a transition from that of arboreal sleep to the building of nests that would secure a more efficient and longer sleeping time to humans sleeping on the ground, enhanced by the discovery and control of fire conferring security to our hominin ancestors (Nunn et al. 2016). The advent of electricity and industrialization made a significant impact on human sleep pattern, and one may argue that the speed of technological evolution and impact on human societal behavior has outpaced the speed of human biological adaption, explaining some of the myriad of sleep disorders (Deboer 2020) and, more commonly, insufficient sleep time, with all the associated health consequences.

Plasticity and Cultural Practices

The impact of plasticity and cultural practices on human disease are two more recent additions to the field of evolutionary medicine. All organisms possess a general capacity for plasticity, for example, the phenotype of an organism may shift in the course of development as genes interact with varying environments (Lea et al. 2017). In evolutionary medicine, there is the acknowledgment that environmental factors may have an impact on human development resulting in changes to health and that plasticity itself is an adaptive mechanism under the influence of evolutionary processes (Lea et al. 2017; Grunspan et al. 2018). Especially important for evolutionary medicine are mechanisms that influence development in response to environmental cues detected during critical developmental periods (Lea et al. 2017). Cultural practices are also acknowledged to have a significant impact on human health and disease vulnerability. These cultural practices may influence evolution (e.g., of humans, pathogens, or other species within our environment) or influence medical practice (e.g., antibiotic, chemotherapy, or caesarean

section frequency within a given population) (Grunspan et al. 2018). In terms of evolutionary medicine, cultural practices are considered an important non-Darwinian (i.e., non-genetic) trait and along with other epigenetic factors (e.g., Handel and Ramagopalan 2010) influence human health and disease in a Lamarckian manner.

Conclusion

The field of evolutionary medicine has contributed significantly toward our understanding of disease etiology and the evolutionary origins of human susceptibility to disease. While this perspective continues to gain interest among specialists, especially biomedical scientists, it is hoped that a growing set of clinicians might use the insight gained from evolutionary medicine to better address the healthcare needs of the communities they serve.

Definition

Evolutionary musicology is a subdiscipline of biomusicology, the study of music from a biological perspective, which embeds the psychological and physiological mechanisms of human music perception and production in the theory of biological evolution. Evolutionary musicology studies the origin and evolution of music in the human species, encompassing vocal communication and musical behaviors in non-human animal species; behavioral, cognitive, and neurological development of musical processing and skill; cross-cultural human universals in musical capacity and cognitive processing; and archeological evidence to develop hypotheses concerning the evolution of human musical appreciation and music-making.

Introduction

Music is a pervasive, universal, and foundational feature of human social life. Although humans appear to be more attuned to the creation and appreciation of this phenomenon than any other

species, the social and biological function of human music has not been fully investigated (McDermott and Hauser 2005). Several scholars have suggested that musical appreciation is a by-product or side effect of properties of the auditory system that evolved for language, general hearing capacity, or other purposes unrelated to music (e.g., Pinker 1997). This view is known as the *byproduct hypothesis*. However, other scholars contend that music-making evolved for the function of social bonding, as human communities increased in size over the course of human evolution (Dunbar 2012; Fitch 2010; Oesch 2019). This view is known as the *social bonding hypothesis*. Although arguments have been made for both perspectives, there is considerable recent evidence in favor of the latter hypothesis. This work falls into three main areas of related research: (1) music and social bonding in non-human primates, (2) music and social bonding in human child development, and (3) music and social bonding in human social interactions.

On the Origins of Evolutionary Musicology

The origins of the field can be traced back as early to Charles Darwin, who first wrote in the *Descent of Man*:

We shall see that primeval man, or rather some early progenitor of man, probably first used his voice in producing true musical cadences, that is in singing, as do some of the gibbon-apes at the present day; and we may conclude from a widely-spread analogy, that this power would have been especially exerted during the courtship of the sexes — would have expressed various emotions, such as love, jealousy, triumph — and would have served as a challenge to rivals. It is, therefore, probable that the imitation of musical cries by articulate sounds may have given rise to words expressive of various complex emotions. (Darwin 1871)

Curiously, this hypothesis of a “musilanguage,” sometimes referred to as a “musical protolanguage,” has been revived and re-discovered repeatedly, often without attribution to Darwin (Brown 2000; Geissmann 2002; Marler 2000). Musilanguage is a hypothetical form of

communication, possibly present in early human cultures, prior to the evolution of modern music and language (Brown 2000; Darwin 1871). The term *musilanguage* suggests a blurring of the distinction between modern human music and language; indeed, most hypotheses suggest that music and language probably co-evolved more or less simultaneously (Brown 2000; Morley 2013; Oesch 2019).

That said, there are challenges inherent in testing this hypothesis directly, as songs and other complex vocalizations do not fossilize or leave behind an archeological record. However, at least one plausible evolutionary trajectory (phylogeny) has been argued, based on modern primate communication systems. Several theorists speculate that the earliest phylogenetic step may have involved nonreferential emotional or mechanical primate signals (e.g., Watts 2016), which was followed by a rough *musilanguage* stage, possibly resembling extant gibbon calls (Brown 2000). Then, hominin song likely came next, developing into music made by primitive instruments and finally resulting in modern language (Dunbar 2012). A more informed view, however, suggests that a spectrum has always existed between music and language, contingent on the species and the ecological context, as the two phenomena coevolved (Morley 2013; Oesch 2019).

Current Competing Hypotheses for the Adaptive Significance of Musilanguage

While it is not fully understood how or why humans developed music or language, an influential proposal known as the *social bonding hypothesis* postulates that both served as adaptations for promoting social cohesion in groups of increasing size and social complexity over the course of human evolution (Dunbar 2012; Freeberg et al. 2012; Oesch 2019). Although other *musilanguage* proposals have been offered, most alternative explanations are at present rather speculative, with arguably less evidence in their favor than the social bonding hypothesis (for a review, see Oesch 2019). For instance, the *investment in*

learning hypothesis argues that individual differences in musical ability allowed for the socio-cultural assessment of biological fitness, as expressed in musical performance (Kirby 2012). More specifically, musical performance could reflect important underlying traits, such as superior cognitive and motor skills, as well as superior economic, temporal, and other resources, thereby providing a unique selective advantage in terms of increased reproductive opportunities. In other words, this hypothesis argues that music-making evolved to be a universal feature of human nature, as evidence of musical prowess was consistently attractive to prospective mates. However, there is currently little evidence for this proposal (Mosing et al. 2015), but see Madison et al. (2018), for a recent exception. An alternative explanation, often referred to as the *kin communication hypothesis*, claims that selection for language came from the benefit of the transmission of information between adults and their offspring (Fitch 2004). However, this proposal is also problematic, not least of which is the fact that both music-making and language are typically used or displayed between non-relatives. A third potential explanation, known as the *coalitional display hypothesis*, argues that human music evolved from animal territorial signals, which eventually became modified into a method of signaling a group's social cohesion to other groups, for the purposes of making beneficial multi-group alliances (Hagen and Bryant 2003). However, this explanation arguably puts the cart before the horse, as it fails to account for how cohesive groups became bonded in the first place, if not through music, language, laughter, and other factors which appear to promote social bonding. Moreover, this explanation also fails to account for why it was music that was critical for such displays, when grooming and spatial proximity appear to signal this information adequately in non-human primates (Keverne et al. 1989). In summary, all three of these proposals suffer from a number of important theoretical and empirical limitations and, at least in their present formulation, appear to be incomplete explanations for the evolution of music and language (Fitch 2013; Kirby 2012; Zawidzki 2006). That said, in the interest of an empirical

analysis based in comparative animal behavior, we now turn our focus to the presence of “musilanguage” in various extant species, as well as why we might be led to expect a common evolutionary origin and history for both music and language.

Music and Social Bonding in Non-human Primates

First, it is important to consider the development of music over evolutionary history. In non-human primate societies, social bonding is achieved through dyadic grooming, facilitated by endorphin-reward activation, as the physiological mechanism that motivates this behavior (Keverne et al. 1989). However, an emergent view suggests that many non-human primates may further supplement social grooming through song or other music-like behaviors, and the same may be true of humans, both in terms of music and endorphins (Oesch 2018, 2019). For instance, Dunbar (2012) has argued that once hominin group sizes became too large to be socially bonded using non-human primate strategies of social grooming alone, music emerged as a mechanism for facilitating social bonding.

Duetting, the most common method of group vocalizations in other animals, is typically described as coordinated song with overlapped phrasing, generally within a mated pair (Haimoff 1986). Duetting has only been documented in a few non-human primate species, particularly Old World primates including gibbons, spectral tarsiers, indri lemurs, and Mentawai langurs. Interestingly, nearly all known cases of duetting are found in the roughly 10% of primate species that are characterized by monogamous mated pairs (Haimoff 1986). In most species of gibbons, for instance, male-female pairs alternate their “songs” while duetting, albeit with significant synchronized phrasing, which appears to facilitate social bonding (Geissmann 2002). Pairs who produce the most highly synchronized duets typically allocate more grooming time, prioritize the same activities, and spend more time in proximity. As lesser apes, gibbons vary from the great apes –

including chimps, orangutans, bonobos, gorillas, and humans – by their monogamous behavior, owed in part to the protracted decade long period critical for child-rearing. Interestingly, the coordinated vocalizations of Mentawai langurs, Madagascan indri lemurs, and spectral tarsiers show a similar pattern, in the relationship between duetting and pair bonding. These primate behaviors are particularly relevant to the evolution of human music and language, given the human tendency toward serial social monogamy and biparental care and our proclivity for forming close non-familial bonds, necessary for bonding the largest societies of any living primate (Oesch 2018, 2019).

In addition, even among polygamous chimpanzees, the presence of pant-hoot chorusing (a form of synchronized sound-making) is generally indicative of the intention for short- and long-term social bonding that is typical of fission-fusion chimpanzee groupings. As in human music-making and conversation, gibbons, chimpanzees, and indris can adjust the pitch, unit duration, timing, and interval duration of their social vocalizations. The presence of chorusing, duetting, and similar calls in these species suggests a case of convergent primate evolution: adaptations to similar social organizations and ecological niches requiring group cohesion (Haimoff 1986). Additionally, duetting in other animals including dolphins, bats, elephants, whales, and naked mole-rats provides further support for music-making as a mechanism of social cohesion. For example, duetting is strikingly common in socially monogamous mated bird pairs; in fact, more than 90% of birds are socially monogamous, and roughly 40% or over 400 species exhibit duetting. Moreover, though original estimates implied an absence of vocal learning in non-human primates, more recent investigations appear to indicate the presence of limited and sometimes complete vocal learning in many non-human primates, suggesting further parallels to human speech and singing. In summary, a wealth of recent studies from comparative animal behavior suggests the origins and evolution of music may be explained in terms of social bonding (for a review, see Oesch 2019).

Music and Social Bonding in Human Child Development

Second, it is important to note the role of music in child development. For example, several developmental studies have shown that infants prefer consonant over dissonant melodies; in some cases, from as early as 2 months old, indicating the human preference for consonant melodies may be innate (e.g., Trainor et al. 2002). Several recent studies have further shown that synchronized action (i.e., behaviors of two or more people occurring at exactly the same time), including synchronized actions set to music, leads to directed helpfulness and cues of group membership. For example, in a study of 4-year-old children, subjects who swung together in synchrony in a swing seat were more altruistic toward their peers, compared to a baseline control condition (Rabinowitch and Meltzoff 2017). Similar results have also been found in infants who bounce in synchrony while held by an adult participant (Cirelli 2018). With respect to musical activities, previous studies have also revealed that singing to infants increases parent-to-infant bonding (Fancourt and Perkins 2018), while other studies have shown that synchronized singing and dancing increases prosocial behavior in 4-year-old children (Kirschner and Tomasello 2010).

Music and Social Bonding in Human Social Interactions

Third, it is important to consider the use of music in human social interactions. Previous research has shown that synchronized musical activities, such as communal singing (Pearce et al. 2015), dancing (Tarr et al. 2016), and drumming (Dunbar et al. 2012), promote social bonding and endorphin activation. Recent theoretical work further suggests this effect may also extend to coordinated action (i.e., behaviors of two or more people occurring in coordination with one another to produce something greater than the sum of the individual parts) music-making (Oesch 2019). In general, coordinated music-making is often standard for most forms of music-making in social

interactions; thus, this is an important area for further inquiry.

Moreover, these effects do not seem to be limited to active, interpersonal musical participation, as merely listening to music from a specific culture can often evoke implicit affiliation toward members of that culture more generally (Vuoskoski et al. 2017), showing that music can be an important part of personal identity formation (Hargreaves et al. 2002). In fact, just hearing music activates several motor areas in the brain (Grahn 2012), pointing to an important biological connection between music and movement, perhaps further suggesting an evolutionary link between music and dance. At present, however, it is poorly understood whether alternative forms of instrumental music-making also facilitate social cohesion, possibly due to the release of endorphins during these activities. An important aim of current research is to uncover whether other music-making tasks facilitate social cohesion, how such tasks compare to equally engaging non-musical social activities, and which aspects are most central for aiding this process, such as synchrony, coordination, rhythm, physical exertion, a steady beat, and endogenous opioids (Tarr et al. 2014).

Direct and Derived Functions of Human Music

Despite much suggestive evidence supporting the social bonding hypothesis, social cohesion is not necessarily the sole function of complex vocalizations, song, or music in humans or other animals. Most evolutionary biologists acknowledge a division between *ancestral* and *derived* traits or functions, also commonly called *direct* and *derived functions* in evolutionary musicology and linguistics parlance (Origg and Sperber 2000). The *direct function* refers to the ancestral adaptive purpose for which a trait has evolved in a particular species, while a *derived function* indicates the trait's co-option for any secondary purpose(s). In the case of music and language, several functions have been suggested, including sexual advertisement (Madison et al. 2018;

Oesch 2017), deception (Oesch 2016), and, of course, social bonding (Oesch 2018, 2019). All of these functions have some degree of empirical support, suggesting they may not be mutually exclusive. However, in comparison to other proposals, there appears to be the frequent and pervasive occurrence of musical and non-musical vocalizations, across a wide variety of taxa, for the function of social bonding. Therefore, it seems more plausible to posit an ancestral rather than derived social bonding function for many of these same vocalizations.

Conclusion

In summary, based on steadily increasing evidence, social cohesion may be the direct function for which music and language evolved. Cultural learning, signaling, sexual display, territorial advertisement and defense, and others are possibly derived functions, expressed in unique ways, contingent on the ecological circumstances.

Evolutionary Neuroandrogenic Theory

Denise Carballea, Dilianna Padron and Isaac Tourgeman
Albizu University Miami Campus, Miami, FL, USA

Definition

Theory that contends that men exhibit more deviancy and criminal behavior than women because of women’s preference for mates that either are able to or appear to provide resources.

Introduction

The evolutionary neuroandrogenic (ENA) theory provides fundamental explanation of the differences between genders in respect to cognition and behavior. This theory has two components; the genetic evolutionary factor which explains the why, and neurology and endocrinology factors which explain the how component. It describes how each sex contributes to the reproductive process and also examines the physiology of sexual differentiation. The theory states that gender differences in cognition and behavior stem from reproductive needs in response to natural selection (Ellis 2011).

Over the years, females have evolved the proclivity to form lasting sociosexual relations with males who are inclined to provide optimal resources. In this theory, it is assumed that females will reproduce more often in following generations if a mate is able to sustain and provide the resources that are needed (Ellis 2011). This does not imply that females who are self-sufficient will

not be able to reproduce successfully, but they will be unable to reproduce as prolifically as those who are able to depend on their mates for resources. Ellis (2011) also stated that populations of females with predisposed genetic biases for males with significant provisioning abilities will be favored by natural selection. The neuroandrogenic theory assumes that these biases may have resulted in the evolution of a broad array of cognitive and behavioral inclinations in males that differ significantly from those of females.

Although these hypotheses lack sufficient supporting evidence, two empirical studies supported the assumption that mate preference is genetically influenced. They additionally supported the premise that females have a higher preference than males do for mates with reliable financial prospects and a desire to make a living, in all cultures studied (Ellis 2011). On the other hand, it is said that males have reproductive options that stem further than adhering with female preferences for loyalty and resource procuring competence. These preferences derive from the evidence that commitment of energy along with the time consumption it takes to reproduce is less crucial for males than it is for females (Johnstone et al. 1996). No correlation between a male's wealth or procuring capabilities and his mate's fertility has been made evident due to the differences between genders.

It is to be noted that several factors will be needed in order to reproduction to be successful. For instance, when it comes to males, fertility can be boosted by having multiple sexual relations. This rarely influences the reproductive success of both sexes. Researchers have also argued that women should evaluate their options "long-term sociosexual alliances" when it comes to solely depending on males provisioning against the likelihood of abandonment after she has provided offspring. Females would be most likely well off with a mate who can moderately provide resources but will be loyal rather than one who is not (Ellis 2011).

The evolutionary neuroandrogenic theory also assumes that there has been an evolution of genetic variants in males, which has led them to respond to female biases toward males who can

proficiently provide resources. It is said that some males have alleles that persuade them to adhere to these biases while other males are genetically predisposed to respond in a deceptive way. ENA theory proposes that there are two functional differences responsible for most differences between genders. One being suboptimal arousal, and the other a right shift in neocortical functioning (Ellis 2011).

Suboptimal arousal determines how quickly people grow weary of stable environmental surroundings. It is hypothesized that when a person is exposed to high levels of androgens the brain satiates on stable conditions more rapidly, a mental state which is referred to as suboptimal arousal. Due to this, those with high androgenized brains seek fewer familiar surroundings, although it may in turn result in discomfort or punishment (Ellis 2011). The function of arousal is regulated by the reticular formation which interacts with both the limbic and prefrontal brain structures.

Rightward shift in neocortical functioning is the hypothesized change in the brain which results from high exposure to androgens, which are male hormones. According to research, it is known that for most individuals, the left hemisphere is more dominant than the right. When males were compared to females, males showed less of a left-dominant tendency than do females (Ellis 2011). It is said that in males, the two hemispheres tend to operate more individually and independently on tasks than females. These minor but significant gender differences in neocortical functioning compose what is known as rightward shift.

This theory also predicts that males will tend to engage in more sexual activity than females. This supports the evolutionary theory that males have the ability to reproduce faster than females by simply having multiple partners. Because of this, males have a greater desire for sexual relations since it will provide a variety of sexual experiences. It is said that gender differences in cognition and behavior between sexes will be small, and due to social learning, attenuation can occur many of these differences (Ellis 2011). The theory predicts that differences between genders derive from reproductive needs that females prefer mates who will provide adequate resources and loyalty.

Several researchers have also discovered that in broad variations of social circumstances, smiling occurs more frequently in females rather than males (Ellis 2006). Articles found offer theoretical reasoning for these differences based on the argument that testosterone as well as other sex hormones have evolved the habit to change brain functioning in a way that hinder males from smiling. This inhibition is seen during phases in their lives in which they are most reproductively active. The theory also assumes that females have been naturally selected to favor males who offer the ability to aid in long-term child bearing when choosing a mate. The focus of this is primarily being able to provide resources. It is also stated that males partly accommodate to this preference by battling with competing males who are also vying for resources, which they will use to attract females. In addition, male smiling is stated to hinder their ability to effectively intimidate their rivals in such situations.

If this theory is equitable, this would mean that genes are involved in promoting the propensity to compete for resources. The Y-chromosome is said to be the location responsible for this (Ellis 2006). As stated previously, these genes are said to operate in part by constraining social signals of fear and submissiveness.

The ENA theory also argues that testosterone alters brain function in a way that shifts the neocortex further from the left hemisphere, which is responsible for prosocial behaviors and friendliness. Due to this shift, the right hemisphere supersedes control, resulting in less social behaviors. Testosterone also seems to affect the dopaminergic and serotonergic system. This type of activity has demonstrated the enhancement of a person's willingness to engage in risky behaviors and also tolerate pain while doing so. This means, dopamine activity is more likely to promote criminality and any other forms of competitiveness in order to obtain resources. Serotonin is also said to be involved with criminality, because low levels of serotonin seem to be correlated with increased criminality due to impaction symptoms of mental illness, for instance, depression (Hoskin and Ellis 2014).

Another theory stemming from ENA theory is the theory of criminal and antisocial behavior and

the effects that androgens have on brain changes, specifically in the subcortical and neocortical regions of the brain (Ellis 2005). Due to females evolving preferences for mates who are or show to be more adequate to provide resources, males have evolved to accommodate this preference by producing higher levels of androgens to enhance this competitiveness (Ellis and Hoskin 2015). The theory claims that since androgens have evolved, these changes evoke in the brain and increases the probability of criminal behavior. This is said to be especially true in those who have been violent in the past or have victimizing types of offenses. ENA theory states that androgen-influenced bodily traits along with muscularity are correlated with criminality specifically offenses that are from a victimizing or violent nature. If this theory was proven to be true, it would mean that higher crime rates will be seen in males as opposed to females.

This theory was tested with a large sample of college students in North America. In the study, as hypothesized, males were seen more involved in crimes than were females. Within both genders, many minor but significant positive correlations were discovered between self-reported criminality and androgen-promoted physiological characteristics. It was noted that self-reported criminality was positively correlated with sex drive, physical strength, body appearance, and masculine mannerisms. There was also a positive correlation with low-deep voice, upper body and lower body strength, and amount of body hair. The regression in males showed that it is possible to statistically eradicate the sex differences in violent crime by including the androgen-promoted physiological traits in the prediction equation (Ellis et al. 2008).

This theory ties into the idea that males have been selected for distinctly competing behaviors and victimization of others because generally speaking doing so would assist them in acquiring the resources needed to ultimately attract mates. It is asserted that criminality is an unrefined form for competitive behavior in order to provide resources, assert status, and gain mating opportunities (Ellis and Hoskin 2015). The neuroandrogenic theory claims that exposure to testosterone along with other androgens is an

important contributor for victimizing behavior. This could be in either the shape of simple business competition or criminality. For instance, this can be seen in everyday business exchanges of services or goods. Criminality would be examples of robbery or assaults which would lead the male to obtain resources (Hoskin and Ellis 2014). From a physiological perspective, the ENA theory states that males are more likely than females to victimize others due to the exposure in their brains to increased levels of testosterone and other androgens (Ellis et al. 2007).

Family factors can also influence one's participation in criminality. The entire nature and extent of the actual influences are uncertain. During the last couple of years, testosterone has been determined a strong contributor to offending in those within their adolescent years. One study conducted by Ellis, sought out to resolve whether two imperative familiar factors are in fact, interacting with testosterone. The two factors that were researched discussed the relationship between amicable parent-child relationships and parental socioeconomic status. These factors are thought to interact with testosterone and perhaps other androgens to influence the likelihood of delinquency (Ellis and Das 2012). Another study looked at self-reported instances of involvement in eight different categories of delinquency in college students in North America. It also looked at the various androgen-related traits such as muscularity and low-deep voice. It took into account the nature of parent-child relationships and parents' social status. Within both sexes, the relationship between androgens and parent-child relations were significantly associated with delinquency. It is important to note that parent social status was not a significant variable. According to the findings, the nature of the parent-child relationship had an effect on delinquency rates (Ellis and Das 2012).

Conclusion

Overall, the neuroandrogenic theory proposes almost all individuals have evolved the propensity to openly compete while searching for resources

and opportunities to mate. This is mostly seen in males due to them being greatly motivated in this regard (Hoskin and Ellis 2014). Females have been stated to have evolved the proclivity to choose males who will be able to provide resources successfully and have the ability to remain loyal, which in turn may reinforce males for displays of control and power that may include deviancy.

University, St. Catharines, ON, Canada

Synonyms

Adoption; Altruism; Evolution; Parenting benefits; Parenting costs; Parenting

Definition

Adoption is generally described as permanently caring for biologically unrelated offspring.

Introduction

Studying adoption practices across cultures and species provides important information regarding general parenting behaviors as adoptive parents, unlike biological parents, do not receive the same evolutionary benefits of parenting as biological parents. Parental investment theory suggests that the high physical, somatic, and social costs of investing in an offspring may be compensated by investing in a genetically related offspring, who can increase parents' genetic fitness (Trivers 1972). Based on this theory, adoptive parents are inevitably missing out on an important evolutionary benefit of parenting, which is maximizing their genetic fitness, while still incurring the high evolutionary costs of parenting. Yet, adoptive behaviors have been found in over 120 species of mammals and birds (Riedman 1982). In fact, there is evidence that parents from one species sometimes adopt offspring from genetically unrelated species (Hrdy 1999). In humans, adoption has been recorded throughout history (e.g., Moses was adopted by Pharaoh's daughter in the bible, and Augustus was adopted by Julius Caesar in Roman history) (Burguiere et al. 1996) and is still prevalent today as approximately 2–2.5% of

children are adopted in the USA each year (Tan et al. 2015). If parenting theories suggest that adoptive parents cannot increase their genetic fitness by investing in adopted children, why are adoptive behaviors still prevalent across cultures and species?

Evolutionary theories provide an explanation by suggesting that adoption may be a form of altruistic behavior. However, this explanation has faced some criticism as some researchers have associated altruistic behaviors with genetic relatedness. For example, Hamilton's (1964) theory of kin selection highlights the importance of genetic relatedness in influencing altruistic behaviors due to the benefit of increasing the frequency of shared genetics in a given gene pool. According to this theory, altruistic behaviors may not have evolved without genetic relatedness. However, Trivers (1971) argued that altruism cannot exist between genetically related organisms and that the cooperative behavior seen between genetically related organisms are rather mechanisms to increase genetic fitness, rather than altruism. Therefore, Trivers defined altruism as cooperative behavior that benefits a genetically unrelated recipient while being costly for the organism performing the behavior. This is adaptive because it benefits the organism performing the behavior in the long run as the recipient of the behavior may return the altruistic act at a later time, known as reciprocal altruism. However, other researchers have suggested that reciprocal altruism may be applied to closely related organisms as there is evidence that even close kin expect reciprocity (Terrell and Modell 1994).

In order for a behavior to be considered a form of altruism, it may be required to meet the following criteria. One of the criteria is that the cost of the altruistic behavior for the organism performing the behavior is relatively small compared to the benefit for the recipient (Trivers 1971). Another criterion is that the cost for the benefactor should still be generally high, so that the altruistic act will have a higher chance of being reciprocated (Tesser et al. 1968). Finally, fundamental evolutionary theories suggest that certain behaviors will

become adaptive if the benefits of those behaviors outweigh the costs based on the organism's life-history features, demographic, and ecological conditions. Therefore, in order to understand adoption practices, it is important to outline the evolutionary motivations behind this behavior by investigating whether or not adoptive behaviors may be driven by altruism according to Trivers' definition.

Before delving into further discussion of adoption, it is important to highlight the difference between adoption and other forms of (non-biological) parental caregiving, such as fosterage and alloparenting. Adoption is generally defined as providing permanent care for genetically unrelated offspring (Terrell and Modell 1994). However, as outlined in the following sections, this definition may not be as stringent across cultures. Fosterage differs from adoption in that it is providing temporary care for genetically unrelated offspring (Volk 2011) although it may be viewed as adoption in some cultures (see below). Finally, alloparenting is when individuals other than the biological parents provide care for the offspring, usually in conjunction with the biological parents (Hrdy 1999). Throughout this chapter, the term adoption is intended as the abovementioned operational definition and will be specified if used otherwise.

In order to understand the motivations of adoptive behaviors and investigate their connection to altruism, the following sections outline some of the key costs and benefits of adoption for the main people involved in this process: adoptive parents, biological parents, and adopted children.

Benefits of Adoption

Benefits for Adoptive Parents: Even though adoptive parents are unable to maximize their genetic fitness, they may acquire other benefits which may explain the prevalence of adoption practices today. First, adoptive parents may be benefiting from filling the void of providing care for biological offspring (Hamilton et al. 2007). Evolutionary theories suggest that some human behaviors may

be adaptive, not due to the behavior itself but rather because they are derivatives of other important behaviors (Hamilton et al. 2007). Thus, the caregiving behaviors seen in adoptive parents toward adopted children may be one such derivative. As ancestral humans frequently lived in close-knit groups where they provided care for genetically unrelated children, adoptive parents today (who usually adopt children due to an inability to produce biological offspring; Riedman 1982) may be predisposed with this "baby lust" (Hrdy 1999), which describes the desire to show parenting behaviors even toward genetically unrelated children. Consequently, adoptive parents may be receiving psychological benefits of love and happiness from raising a child (Volk 2011).

A second benefit for some adoptive parents may be increasing their genetic fitness by adopting children within the kin as form of kin selection (Hamilton 1964). Adoptive parents in most modern western countries are shown to adopt kin more often than non-kin in cases where the biological parents are deceased, have a lack of resources to provide for the child, or are neglectful toward the child (Volk 2011). In addition, when biological parents decide to give up their child for adoption, they are shown to prefer kin, rather than non-kin, to adopt their child with the notion that genetic relatives will provide better care for the child. This is seen in various cultures including the Kiribati of the Gilbert Island, West Africa, Brazil, and Peru (Volk 2011). In addition, transgendered uncles in Samoa, known as *fa'afafin*, are shown to provide alloparental care to kin (VanderLaan et al. 2015). Although this is not strictly adoption by definition, the predisposed motivation behind this behavior is noteworthy. VanderLaan and colleagues suggest one explanation for the increased caregiving behavior toward niece and nephews seen by the *fa'afafin* is adaptive as it may be the only opportunity for the *fa'afafin* to maximize their genetic fitness.

However, there are many instances where parents with biological children choose to adopt additional children. For example, adoption in Inuit societies frequently occurs when biological parents want to abandon or kill their infants (usually

due to less resources), but do not do so due to other members of the community who volunteer to adopt the child, even if they have their own biological children (Terrell and Modell 1994). In addition, in African-American communities, families usually have a biological and a social father, where the social father is sometimes seen as more important to the child compared to the biological father (Furstenberg 1995). In these cases, it may be other benefits that are driving caregiving behaviors in adoptive families, such as of gaining economic resources and social networking.

Therefore, a third benefit for adoptive parents may be increased economic resources through the adopted children. This is theorized to be the most common reason for adoption in ancestral humans (Volk 2011). Adoptive parents can receive direct economic resources from the adopted children when the adopted children serve as future providers and/or workers for the family. For example, adopted children among the Baatombu of West Africa (Silk 1987) and in Wogeo (Volk 2011) serve as extra manpower for cheap labor and kin support. Also, among the Yupka of South America and the Yap in Micronesia, parents most often adopt children in order to provide care and support to the elderly (Volk 2011). Similarly, children on the Mandok Island of Papua New Guinea are adopted with the purpose of providing economic resources for the adoptive parents when they are older (Terrell and Modell 1994). Adoptive parents can also increase their economic resources indirectly by forming alliances with the biological parents of the adopted child. For example, adopting children among wealthy families in Britain and Ireland has been shown to be a method of securing political links (Volk 2011). Similarly, among the Yap, adoption is used to trade or access land. In addition, adoption may also be used to transfer familial dynasty in the absence of biological children in various cultures (Volk 2011).

A fourth benefit for adoptive parents may be the opportunity for social networking by forming and strengthening social bonds with the biological parents of the adopted child (Volk 2011). In Oceanic societies, such as Hawaii, adoption is relatively more common in comparison to Western societies and is a method to adjust for the large

family sizes and low economic resources (Silk 1980). Adopting a child from another family in these cultures establishes friendships and creates social networks. However, unlike most Western adoptions, the adopted children in Oceanic societies continue to maintain emotional bonds with their biological parents, possibly so that the biological parents can ensure that their children and receiving adequate care as adopted children may not always be treated well by the adoptive parents (Silk 1980). Adoptive parents may also benefit from social networking by using adoption to resolve conflicts. For example, Roman kings adopted princes from other countries in order to resolve conflicts and form political alliances with other countries. Similarly, parents in the Wogeo adopt children as a form of settlement with the notion that an individual is less likely to attack you if you are caring for his biological child. Adoption can also increase social networking by securing brides for the biological sons. For example, one of the most common reasons couples in China adopted a girl was so that their infant or future sons could marry her (Johnson 2004). In addition, older men among the Yupka adopt girls in order to marry them once they reach puberty (Volk 2011).

Fifth, adoption practices may help with the transmission of social learning. This may not be directly adaptive for the adoptive parent. However, it may benefit the parents' genetic fitness. In most mammals and birds, parents are shown to transfer decision-making strategies related to mate preference, predator avoidance, and food preferences to their offspring (Avital et al. 1998). This is especially adaptive for the genetic relatives if the parent has a socially transmittable trait that is unique from the general population as parents can transmit these socially transmittable traits to other members of their close-knit community and consequently increase the kin's survival rates, along with the parents' genetic fitness. The transmission of these traits can be amplified by transferring them to biological offspring, as well as adopted offspring (Avital et al. 1998). This behavior is seen in the communal caregiving observed in cats and mice, where when the biological parent is killed or injured, an adoptive parent replaces the

biological parent in order to increase chances of the litter's survival. The young in the litter consequently learn this behavior and transfer it to their future adopted and biological young. Although, there is less research on how this theory may be applicable to humans, the practice of adoption itself has been theorized to be spread through the transmission of such social learning practices (Avital et al. 1998).

Benefits for Adopted Children: In addition to benefits for the adoptive parents, adoption may also have benefits for adopted children. The most important benefit for adoptive children may be increasing their chance of survival in the absence of care from their biological parents (Avital et al. 1998). This is especially important when the children are young and require adult care to reduce risks for mortality (Volk and Atkinson 2013). Moreover, adopted children usually have better chances of growth, development, and survival in the care of adopted parents compared to their biological parents as adoptive parents in typical Western societies are relatively young (30–40 years), educated, and wealthy (Volk 2011), while biological parents that give up their children for adoption usually have less resources to provide for the offspring (Brannan and Gillet 2005). In fact, it is suggested that adopted children may seek out adoptive parents who have relatively more resources compared to their birth parents (van Ijzendoorn and Juffer, 2006). For example, children in adoption agencies have shown to influence the choices of potential adoptive parents by acting more friendly with those they wanted to be adopted by and more violently toward those they did not want to be adopted by.

Benefits for Biological Parents: Adoption would not exist if biological parents did not give up their children for adoption (with the exception of cases where the biological parent dies or children are stolen from biological parents; Hrdy 1999). However, why would parents give up the opportunity to maximize their genetic fitness by abandoning their offspring? One explanation is because biological parents benefit from receiving free care for their offspring while increasing their own genetic fitness (Volk 2011). For example, majority of children who are given up for adoption

are shown to be from unmarried mothers with less social and economic resources (Brannan and Gillet 2005). In addition, poor families in Huan Warle, Jamaica, and Claudia Fonseca in Brazil give up their children for adoption due to the inability to provide for them (Reidman 1982). Further, adoptive parents may sometimes provide financial compensation to the biological parents in exchanged for their child (Volk 2011).

Another benefit for biological parents may be freeing up time, energy, and resources to produce and invest in another offspring (Volk 2011). This is an evolutionarily better alternative compared to killing the infant due to the inability to provide for the infant and the infants' perceived low chance of survival (Brannan and Gillet 2005). By having the adoptive parents care for the offspring, biological parents are increasing their genetic fitness by ensuring the survival of two or more offspring while only investing in one. This theory is supported by traditional cultures in the Western Caroline Islands who are shown to give up their biological children to be raised by others in order to have increased availability of resources to invest in their remaining biological children (Volk 2011).

Adoption also comes with the following costs for the adoptive parents, biological parents, and adopted children.

Costs of Adoption

Costs for Adoptive Parents: An evolutionary cost for adoptive parents is investing time, energy, and resources in a genetically unrelated offspring without increasing their genetic fitness (Trivers 1972). From an evolutionary perspective, this is the most substantial cost for an organism. Another cost for adoptive parents is making an increased effort of creating a parent-child relationship due to the lack of genetic relationship, which may deplete energy, time, and resources that can be conserved for other vital functions. Further, adoptive parents also face the possibility of the adopted child seeking to connect with his/her biological parents and eventually deserting the adoptive parents (Volk 2011). In this situation, adoptive

parents lose any social benefits that they could have acquired from the adopted child. As a result, the abandonment of the adopted child may cause emotional grief for the adoptive parents. Possibly for this reason, many adoption agencies follow closed adoption practices (Volk 2011).

Costs for Biological Parents: The evolutionary costs for biological parents may be risking improper care of their offspring by the adoptive parents. In nonhuman animals, a biological mother may immediately take back her offspring if they are inadequately cared for by the adoptive parent (Hrdy 1999). Due to this risk, biological mothers among the Massai in Kenya, who are sometimes required to give up their biological baby to an infertile woman within the kin, are shown to strongly protest against this practice (Volk 2011). In addition, Brazilian mothers who unknowingly gave up their infants for adoption are shown to still experience grief and sadness due to the inability to retrieve their children. Therefore, the separation from biological offspring may have emotional costs for parents as it may create feelings of loss and void, which can sometimes lead to long-term depression (Brodzinsky 1990).

Costs for Adopted Children: A social cost for adopted children is being cut off from the biological parents, which may elicit perceptions of lost identity (Brodzinsky 1990). Adopted children in international and transracial adoptions may also lose touch with their cultural roots when adopted by parents with different cultural backgrounds (Terrell and Modell 1994). In addition, in families that consist of both biological and adopted children, the adopted child may feel secondary to the biological child (Silk 1980). For example, studies have found that sibling comparisons between the adopted and biological children may result in feelings of jealousy and/or envy for the adopted child (Brodzinsky 1990).

Is Adoption a Form of Altruism?

Based on this brief list of the costs and benefits for adoptive parents, biological parents, and adoptive children, it can be argued that adoption is indeed a form of altruism. First, it can be suggested that

adoption is a form of altruism because the cost for the adoptive parents (inability to maximize genetic fitness, depletion of resources in creating a parent-child relationship, and potential abandonment by the adopted child) is relatively minor compared to the collective benefits for the adoptive child (maximizing the child's survival and genetic fitness) and his/her biological parents (maximizing genetic fitness). In addition, the altruistic behavior by the adoptive parents may also have a high chance of being reciprocated by the adopted child as the costs for the adoptive parents are generally high. Finally, based on adoptive parents' greater ability to provide for the adopted child (relatively more resources and maturity compared to the biological parents), the benefits of the adoption may outweigh the costs for adoptive parents.

However, while the evidence above suggests that adoption may be a form of altruism, there is also evidence which suggests otherwise. Most parenting behaviors are shown to be instinctive across species (Hrdy 1999). For example, first-time mother mice that do not have any previous parental experience are shown to instinctively clean the embryonic fluid, eat the placenta, and lick the pups (which helps to facilitate the pups' healthy development) after giving birth. This instinctive behavior is theorized to be associated with increased levels of oxytocin in the mother mice right after giving birth. Similarly, in humans, high levels of oxytocin, along with other pregnancy-related hormones, are found in new parents, which is theorized to increase caregiving behaviors (Champagne 2008). However, adoptive parents do not have such pregnancy-related hormones to trigger caregiving behavior. So how are adoptive parents able to show good parenting behaviors? One explanation is that since adoptive parents face much stigma (see below), they may be compensating for it by trying to prove that they are good parents (Volk 2011). Another reason could be due to the long administrative process of completing the adoption process, which may psychologically commit adoptive parents to create a long-lasting family (Volk 2011). While these social factors may be influencing the positive caregiving in adoptive parents, another possibility

is that adoptive parents are influenced by forced perceptions of genetic relatedness.

Forced Perceptions of Genetic Relatedness

Forced perceptions of genetic relatedness seen in the adoption process may be one argument against adoption being a form of altruism. There is evidence that various mechanisms may simulate genetic relatedness between adoptive parents and adopted children. One mechanism may be kinning (see chapter ► [“Paternity Uncertainty and Investment in Sons and Daughters”](#)), in which adoptive parents make an increased effort, more than biological parents, to explicitly and frequently expose the adopted child to members of the immediate and extended family in order to increase emotional bonding and perceptions of relatedness. This increased exposure may also influence stronger perceptions of resemblance and kinship (Volk and Atkinson 2013). If adoption is unrelated to altruism, this behavior may be risky as adopted children could face mistreatment and abuse from adoptive parents due to the lack of genetic relationship (Daly and Wilson 1996). In fact, it is theorized that this risk may be increased when a child does not resemble his/her adoptive parents (Terrell and Modell 1994). Therefore, facial resemblance between the adoptive parents and the adopted child may be another mechanism that simulates perceptions of genetic relatedness and consequently influences motivation for caregiving behaviors (see chapter ► [“Resemblance”](#)). For example, studies have found that hypothetical adoption ratings are correlated with high levels of facial resemblance between the adult and child, especially for men (Volk and Quinsey 2002). In addition, practical studies on parenting have found that fathers invest more in children with high levels of facial resemblance (see chapter ► [“Paternity Uncertainty and Investment in Sons and Daughters”](#)). Further, adoption agencies are found to match the adopted children with adoptive parents based on the degree of facial resemblance between the adopted child and adoptive parents (see chapter ► [“Paternity Uncertainty and Investment in Sons and Daughters”](#)).

Other facial cues in children may also be influential in parents' adoption decisions, such as age and health. With regards to age, adults are shown to have a general preference to adopt younger children. Indeed, studies show that approximately 84% of unrelated adopted children are under 11 months old (Brannan and Gillet 2005). Hrdy (1999) suggests this to be the result of vulnerability seen in the infantile facial cues in young children which influences adults to be attracted to and care for young children. Additionally, social perspectives suggest that preference for younger adopted children may also be associated with younger children being easier to assimilate into the family as older children may come with previous life experiences which may be challenging to form parent-child attachments (Brodzinsky et al. 1995).

However, infants have higher changes of mortality compared to older children (Volk and Atkinson 2013). Therefore, the predisposition to invest in the youngest children may be overpowered by cues of good health. Studies show that adoptive parents frequently review the adopted child's medical history, especially during international adoptions (Volk 2011). Moreover, a photograph of the child is sometimes analyzed by medical professionals to assess the adopted child's health (Volk 2011). Assessing children's health through facial cues is also shown to be used during hypothetical adoption decisions (Volk and Quinsey 2002). In these studies, children with normal body weight are shown to receive higher hypothetical adoption ratings compared to children with lower and/or higher than average body weight. Possible explanations for this could be that children born with extremely low body weight may be associated with health problems such as difficulty gaining adequate weight when older. Similarly, children who are above average in weight are also at risk for health problems such as gallstones and hepatitis (Whitlock et al. 2005). In addition to body weight, abnormal facial features are also shown to negatively influence hypothetical adoption ratings (Waller et al. 2004) and possible explanations for infant abandonment. This may be because abnormal facial features may be a proxy for low genetic fitness.

Conclusion

The goal of this chapter was to determine whether or not adoption may be a form of altruism according to Trivers' (1971) definition of altruism. Although some evidence suggests that adoption maybe a form of altruism, there is also evidence to the support the argument that adoption may not be a form of altruism and may rather be driven by forced perceptions of genetic relatedness. Although inconclusive with regard to the relationship between adoption and altruism, the evidence presented in this chapter suggests that adoption may be a multiply determined construct, as is general parenting, and thus may be motivated by various (altruistic and non-altruistic) factors (Bjorklund and Pellegrini 2000). This chapter also depicts that even though there is much evidence that adoptive parents are just as capable of providing care for adopted children as biological parents are, adoption is still viewed in a negative light.

Even though the percentage of adoption rates continues to increase (Tan et al. 2015), there is a general negative stigma associated with adoption, such as perceptions of adoption being second best to biological families (Terrell and Modell 1994). One reason may be that because parents usually adopt children due to an inability to produce biological children (Volk 2011), adoption may be associated with infertility, which is looked down upon in various cultures. For example, in India, adoption is shown to be a last resort and may only be acceptable when fertile couples adopt children in addition to their biological children (Bharadwaj 2003). In addition, some parts of Egypt have strict prohibition laws against any form of adoption (Inhorn 1996). Another reason may be that these negative perceptions may be stemming from historical stigmatizations of mothers who had children out of wedlock (Volk 2011).

The negative stigma associated with adoption is also reflected in the terminology around adoption, such as real parents vs. adoptive parents (Hamilton et al. 2007). In addition, adoptive parents are perceived to be inadequate parents and consequently have lower levels of self-esteem regarding in their parenting skills. Further, it is assumed that adopted children have less healthy

hereditary genes compared to biological children. Finally, even most researchers studying adopted children most often take a negative view of adoption such as studying the mental health problems of adoptees and risks for adopted children (Hamilton et al. 2007).

This negative stigma associated with adoption may be due to the relatively less research on this adoption in comparison to alternate forms of family structures (Hamilton et al. 2007). Therefore, in order to further understand adoption and help reduce the stigma associated with this form of parenting, more studies need to focus on the positive aspects of adoption. For example, future studies should explore adoption practices across in more cultures in order to gain a deeper understanding of adoption and general parenting motivations. In addition, future studies should investigate the relevance of certain adoption theories, such as transmission of social learning, in humans by investigating if adopted children are more likely to be adoptive parents themselves and the forms of social traits that may be transmitted through adoption in humans. Finally, more studies should study adoption from an evolutionary perspective as evolutionary theories help understand the adaptive responses of adoptive practices (Bjorklund and Pellegrini 2000).

Evolutionary Paradox: Women Choosing Not to Have Children

Amanda DeSantis

Detroit Mercy, Detroit, MI, USA

Synonyms

Childless women; Evolutionary contradiction;
Reproductive fitness

Definition

The catalyst for evolution is the propagation of one's genes. In modern times, women are choosing to have less or no offspring, which is seemingly an evolutionary paradox.

Introduction

Females are the choosier sex in almost every species. In modern times, the argument could be made that as a result of more women obtaining college degrees and high-paying jobs, less high mate value males exist (Buss 2016). As a result, human females are having to choose whether to copulate with lower mate value men or whether to take themselves out of the mating game entirely. With mortality rates at an all-time low and economic stress at high, parents may also be choosing to invest more resources in fewer offspring. Additionally, with the advent of modern birth control, women can have sex without the consequence of pregnancy. While the drive for sex still exists, the consequences are more variable, giving women a choice they have never had before.

Reproductive Fitness

When it comes to choosing a mate, women are often much choosier than are men. This is a result of women's greater initial investment in reproduction (Trivers 1972). This difference begins at the basic level of sex cell size. Women's sex cells are larger and packed with nutrients and are in fixed and non-replenishable supply. Men's sex cells are much smaller and replenish at about a rate of 12 million per hour. Additionally, women's greater investment continues with 9 months of gestation, followed by lactation, and several years of caring for their offspring which may close off any possibility of other mating options. Men's investment, however, can end with fertilization, opening them up to other mating opportunities immediately. As a result of this great disparity in initial parental investment, women are valuable and will not allocate their reproductive resources indiscriminately (Buss 2016; Trivers 1972).

Female reproductive opportunities are also limited as it takes 9 months to have at least one child, and a woman can only have a limited number of children as she has a limited number of eggs. In contrast, males' reproductive opportunities can be fruitful and are dependent on

available and willing fertile females. Ancestral women who were indiscriminate about mates would have experienced lower reproductive success and therefore would have had less children survive to reproduce. As a result of the sex discrepancy in human parental investment, evolution favored women who were more selective about their mates because women in the evolutionary past risked enormous investment by having sex. Men, on the other hand, lose only a few minutes or hours of time and can move on to a new coupling. While gender equality and modern birth control methods have drastically changed these costs and benefits, sexual and mate preferences evolved over millions of years, and thus, modern humans still possess this underlying sexual psychology despite environmental changes (Buss 2016).

Evolution has also favored women who prefer men who possess certain adaptively valuable characteristics and who are likely to confer the most benefits, while they dislike men who possess poor attributes that confer costs (Buss 2016). A woman choosing a mate will likely begin by analyzing her own individualized needs. She will then identify and evaluate the potential mate's qualities followed by integrating her knowledge about each potential mate to determine the best candidate (Buss 2016). Several characteristics women look for in a potential mate include resource potential, commitment, social status, men who are older than they are, ambitiousness and industriousness, dependability and stability, intelligence, compatibility, size, strength, V-shaped torsos, symmetry, masculinity, love, and kindness (Buss 1989; Langhorne and Secord 1955). In short, women who preferred men who were reliable and willing to commit to a longer-term relationship were more likely to have children who survived and thrived.

Even in the more gender equal modern environment, women favor men who have professional degrees, are financially successful, have high social status, have greater intelligence, and are tall, independent, and self-confident. This is especially true for women who are highly educated and financially successful themselves. Again, this is accounted for by the fact that sexual

selection takes millions of years to develop and is not easily changed by the modern environment. One of the most important characteristics to women is commitment as conceiving a child when support is unavailable would be detrimental to reproductive fitness for the female. Committed males also bring with them resources that they are willing to provide to their chosen mates and her children (Buss 2016).

Operational Sex Ratio

One reason why women may be choosing not to reproduce is the current operational sex ratio. The operational sex ratio is the ratio of sexually active males relative to the number of fertile females at a given time (Buss 2016). This sex ratio is said to affect the ways in which females compete with other females and males compete with other males for mates. For example, whether men and women choose to utilize short-term or long-term mating strategies is in part related to the operational sex ratio. If there are more sexually active males in the population than there are fertile females, females can afford to be more choosy, male intrasexual competition will increase, and long-term sexual strategies will be the norm. If there are more fertile females than there are sexually active males in the population, women cannot afford to be as choosy and will have to compete with each other for the small number of most desirable men, and short-term sexual strategies will be the norm (Buss 2016).

Many factors affect the operational sex ratio. Some examples include wars in which more males than females are killed, risky behaviors such as fighting which occur more frequently with men, homicide which affects more men than women (both in being perpetrators and victims), and differential marriage rates by age in which women remarry less and less often than men with increasing age. In scenarios in which there are many available men in relation to fertile women, many men will be excluded from mating (Buss 2016). The men who can attract women in these conditions will jealously guard their mates against potential rival mates. This ties into an

evolutionary theory about rape which suggests that some men will turn to rape and sexual aggression to gain what they cannot with their current mate value. In situations in which available fertile women are in short supply, long-term sexual strategies become the norm because males have no choice but to appease the available females by committing and providing.

The change in the ratio of men to women throughout life can cause a shift in mating strategies. Younger men have less access to available (young, attractive, fertile) women because these women prefer men with higher status and more resources, something that older men tend to have. As a result, it seems that younger men engage in risky competition behaviors such as committing violent crimes of sexual coercion, robbery, battery, and murder. As men age, the ratio between the sexes tilts into their favor. If they have managed to survive the risks associated with intrasexual competition and have upped their mate value through increased status and resource attainment, they will have a larger pool of potential mates to choose from (Buss 2016).

The possibility that short-term mating is on the rise can be explained by a theory that states that the unbalanced sex ratio among college-educated individuals suggests a lack of eligible men and a rise of eligible women. In this scenario, men are able to shift to short-term sexual strategies because the sex ratio is in their favor and they are able to “implement their desire for variety” (Buss 2016, p. 125). Women in this scenario do not have much choice but to shift to a short-term strategy as well because there is shortage of men who are willing to invest or commit. Similarly, in populations or contexts in which there is little benefit for women to commit to one mate, the females will shift to a short-term strategy. Some examples include if a woman’s kin provide her with more resources than could a potential mate and if pursuing multiple short-term sexual relationships will provide her with resources from multiple men, or cultures in which food or other resources are shared communally (Buss 2016).

The college sex ratio imbalance, therefore, leads to a scenario in which many women

compete for the limited amount of high mate value men and thereby many are left to settle for short-term or casual sexual relationships. Additionally, because there are fewer men than women on college campuses, men don't have to commit to one woman or provide for her at all. They are freer to pursue multiple mateships because women cannot afford to lose out on the opportunity of mating with the only high mate value males in the population. This puts women at a great disadvantage if they do choose to reproduce because there is no guarantee of commitment (Buss 2016).

Childcare Conditions

Lack of commitment and paternal investment, particularly financial, is one reason cited by women who have had abortions (Hill and Low 1992). Furthermore, because women's sexual strategies have developed over millions of years with the idea that some men, because of a lack of resources, social status, etc., are not worth copulating with, there may be some evolutionarily derived psychological mechanism that is stopping women from choosing to have children in this current sex ratio. In other words, females have evolved to be choosy when selecting a mate to reproduce with, such that they want to make sure the men they choose are committed, have many resources, and are willing to give women and their children those resources. In the modern age in which more women are educated and therefore may be more financially independent than women of the past, they are having a much more difficult time finding high-quality mates (Buss 2016). These evolved mechanisms also make it less likely that women will want to raise children on their own.

Even though women have taken on new economic responsibility and have become increasingly more educated than women of past generations, women are still primarily responsible for childcare (Hill and Hill 1990). As a result, women must sometimes choose between staying home to rear their children, thus losing out on learning important work-related skills, or taking a job with flexible hours and does not require

travel, which likely does not pay well (Hill and Hill 1990). A third option is to opt out of childbearing entirely, whether deliberately, to concentrate more time to other activities such as work, or because there is no time to have and care for children. Mothers who work tend to face scheduling conflicts, dealing with family issues while at work, and missing days (Hill and Hill 1990). For men, only single fathers face these same issues at a comparable rate (Hinde 1971). Hill and Hill (1990) suggest that in order for women to participate in the job market equally, either economic activities must be carried out concurrently with childcare or the extent to which mothers bear the primary responsibility for childcare must be reduced. It can be theorized that since neither of these suggestions has become a reality, many women are choosing to opt out of childbearing altogether.

Other Reasons

Older women are forced to compromise their mating strategies by lowering their standards, becoming more competitive by enhancing their appearance, securing resources on their own, or opting out of the mating market altogether (Buss 2016). Choosing to opt out of mating rather than meeting these demands can also help explain the increase in childless women. With women obtaining more professional degrees than men, women are getting married or seeking long-term relationships at older ages. As a result, they may have difficulty attaining a high value mate due to being less fertile, less physically attractive, and less young looking. Rather than becoming more competitive to attain a mate, they may just choose to fill their lives with other meaningful things.

Another reason why women may be choosing not to reproduce is the advent of birth control. Until recently, sex and reproduction were inextricably linked. Modern birth control methods have changed the outcomes of having sex, but not the mechanisms behind why humans decide to engage in it to begin with. Sex is perceived as being pleasurable because it enhances reproduction (Low 2015). This is known as a proximate

cause which tends to drive the system, while sexual selection acts as a passive filter (Low 2015). Evolution has selected individuals who enjoy sex because those individuals had children who also had interest in sexual activity. While people are likely still interested in sex, birth control gives women a choice of whether they'd like to be mothers. It creates a possibility in which men and women could be on equal footing in which sex does not equate to parental consequences (Low 2015). In other words, selection pressures are unable to exert the outcomes of pregnancy on women who want or enjoy sex mainly because we operate on proximate causes as selection pressures are lost to our subconscious (Low 2015). The link between sexual pleasure and parenthood has not been broken.

Abortion is another option that potentially overrides selection (Low 2015). While women may be engaging in sexual activity at the same rate or even at a higher rate than they historically have, the outcome of sex no longer must be pregnancy, and pregnancy no longer must result in a child. Additionally, it may be that women do not develop a desire to nurture and be a parent until after their child is born and the release of oxytocin, the hormone that is related to bonding (Elgar 2015). Therefore, women are still fulfilling the demands of their evolved psychological mechanisms to copulate, but due to modern advances, they are not actually reproducing. Women now have the room to make personal choices about whether or not they want to be mothers, something that is not true in evolutionary history and has not been accounted for in the literature (Elgar 2015).

In addition to individual women choosing not to have children, the birth rate as a whole has also decreased (Low 2015). Some proximate causes of the low birth rate include factors affecting exposure to copulation, factors that deliberately control fertility such as birth control, and natural fertility factors that exclude birth control and abortion (Bongaarts 1978). In terms of exposure to copulation, women who are not in sexual relationships for most of their reproductive years and who have children at later ages will have less children (Low 2015). In terms of deliberate control of fertility,

there are temporary means of birth control such as condoms or the pill, as well as more permanent means such as vasectomy and tubal ligation (Gray and Anderson 2010). Elective abortion is another method of birth control. It is seen in a U-shaped distribution with young women in their teens who are not ready to have a family and have not secured male commitment and women in their 40s who have already achieved their desired family size and risk complications in their pregnancies being at either end (Hill and Low 1992). In the middle are women in their 20s and 30s. Natural fertility factors include factors such as erectile dysfunction, low coital frequency, and sterility (Gray and Anderson 2010). These combined factors have led the average fertility of many nations to fall below the replacement level or having two children in order to replace both the mother and the father (Gray and Anderson 2010).

An anthropological theory introduced by Bobbi Low proposes that since mortality has decreased, individuals tend to invest more in a lower number of children since they are likely to make it to reproductive age (Low 2015). As a result, birth rate has decreased. In addition to this, economically, it is more difficult for men to accrue the abundant number of resources needed to care for a child in modern times. With the cost of living and education having increased, parents are more likely to have less children and put all their resources in these few offspring. However, a caveat is that men with more resources are always more fertile than men without (Low 2015).

Low (2015) suggests that hunter-gatherer societies (as illustrated by current societies of this nature) likely experienced both high fertility and high child mortality. Industrialized society has brought about a "demographic transition" which can be characterized as having low fertility as well as low mortality (Low 2015). In these modern times, both marital status and a number of existing children play a role in individuals' deliberate fertility decisions (Low 2015). Other factors that have an effect include whether the government offers tax breaks or taxes fertility. As stated, working to increase one's wealth has harsher trade-offs for women than it does for men (Low 2015).

Demographic transitions are often a result of factors such as education and wealth (Gray and Anderson 2010). This seems to be supported by the numbers which point to more educated countries having lower fertility than less educated countries (Gray and Anderson 2010). The number of offspring an individual has is no longer a good predictor of reproductive success as each of these offspring will be so costly (Low 2015). However, less educated and poorer women have more children than their more educated, richer counterparts (Low 2015). Likely, this is because children of lower-income less educated women face higher mortality rates which brings about a quantity over quality strategy, whereas higher-income more educated women take a quality over quantity strategy and tend to invest heavily in only a few children (Low 2015). This does not mean that those with incredible wealth can reproduce boundlessly, as fertility is bound to decline as per capita investment in children continues to rise (Smith et al. 2010).

Other theories such as one by Caldwell (1976) posit that children may be a form of retirement insurance in countries or areas in which social security does not exist. Theories such as this suggest that one benefit of having children years ago was that they could participate in labor and that they could be helpful to parents when they became too old to work (Gray and Anderson 2010). It would therefore be less fruitful to have many children today as children spend many years in school before they can be economically beneficial to the family (Gray and Anderson 2010). In conjunction with this theory, evolutionary theory would suggest that a strategy in which parents funnel their resources into their children until they become too old and then those children funnel their resources into their parents is one that natural selection would likely have favored (Kaplan 1996).

Conclusion

The objective of human evolution is the propagation of one's genes. However, in the modern world, the birth rate has continued to decrease in

industrial societies. One factor affecting the low birth rate may be women's choice not to reproduce. This begs the question of why women would not want to have children. Thus far, research suggests that due to an increase in low mate value men and a decrease in high mate value men, women are having more short-term relationships which are not conducive to raising children. In addition, with mortality rates decreasing and economic stress increasing, women may choose to reproduce less in order to invest more resources into less children. Lastly, with the rise of modern birth control, women are no longer as restricted in having sex because pregnancy is not the mandatory outcome. Future research should continue to investigate these factors.

Definition

A field of study that merges personality and evolutionary psychology research with an emphasis on understanding both the universality of personality traits and its variation across individuals

Introduction

One of the most significant questions that psychologists across multiple fields attempt to answer is, “why are there no two persons who are the same?” Why are some people more dominant and assertive while others are more shy and withdrawn? Why are some people more agreeable and friendly while others are more hot-tempered and aggressive? Approaching these questions about personality through an evolutionary lens may help researchers, professionals, and lay people alike to better understand *why* individual differences exist across people and cultures, and differ within populations, by focusing on the ultimate functional causes of this variability. In taking an evolutionary perspective, personality and individual differences can be situated and comprehended as beneficial for the survival and reproduction of ancestral humans, illustrating the nonarbitrary instances of how selection has shaped us. Furthermore, by focusing on the adaptive qualities of conventionally “maladaptive traits,” an evolutionary perspective seeks to understand why such traits are advantageous, rational, and useful strategies under certain environmental contexts.

The profound consequences of these differences between individuals are not limited to our ancestors. Even among contemporary humans, differences in personality may predict how long an individual will live, what kinds of relationships that person has with others, how long these relationships will last, how many children a person will have, and what kind of parent a person may be. Furthermore, personality characteristics are also associated with how humans situate themselves in relation to the world. For example, personality differences may influence how individuals believe society should be organized (i.e., political affiliations) or the relationship they perceive between themselves and a higher power (i.e., religiosity; see Buss 2009 for review). In this regard, personality is often seen from an evolutionary personality psychological perspective as a series of adaptive options that organisms may have from which to choose in calibrating themselves to their environments. This is not unique to

personality traits, nor is it unique to humans; the process of adaptive calibration that occurs through development adapting an organism to their environment is a theme observed throughout nature (e.g., Nettle 2010; Stearns 1992).

Personality as an Instance of Developmental Adaptation

On average, any given personality trait has heritability estimates of about 50% (Bouchard and Loehlin 2001). However, much of the observable variation in personality traits appears to come about through salient early-life experiences that may induce long-term and stable changes by interacting with the organism's biological predispositions (discussed further in section "Genes and Personality"). Responsiveness to early environmental cues may therefore be adaptive when the cues that are present to an organism during development are able to represent future conditions moderately well (Stearns 1992). For example, consider a species of freshwater snails, *Physella virgata*, that are prey for both fish and crayfish. Each of these predators leaves its own distinct chemical signature in the snails' environment. This chemical signature is thought to trigger a cascade of developmental events that optimizes the snails' defenses against the predators that they are likely to encounter. Consequently, snails who encounter fish will benefit from developing rotund shells that are difficult to bite and the ability to leave the water. Similarly, snails who encounter crayfish will benefit from growing narrow shells that are difficult to enter, and faster shell maturation to defend against vulnerability (DeWitt et al. 2000). The differing development of the same species of snails under different conditions suggests that certain phenotypes may be packaged together *strategically* by natural selection to give the organism adaptive advantages. These clusters of traits, or *behavioral syndromes*, are observed across the animal kingdom (Nettle 2010). Similarly, human personality traits appear to cluster together to solve adaptive problems. The leading theory that conceptualizes and explains personality

and individual differences in humans using developmental adaptation is life history theory.

Life History Theory

Life history theory (LHT) is an evolutionary-biological metatheory that describes individual differences as reflective of a series of coordinated adaptive trade-offs that organisms must make to maximize their allocation of the limited resources that are available to them in their environment. The ability to pursue the "optimal" life history strategy for one's environment is associated with increasing one's evolutionary fitness (e.g., Stearns 1992). LHT is generally concerned with resource trade-offs in two categories: (1) somatic effort (i.e., having to do with growth and maintenance) and (2) reproductive effort. Within reproductive effort, there are two subcategories: (1) mating effort (i.e., seeking out a mate, establishing pair bonds) and (2) parental effort (i.e., gestation, childbirth, breastfeeding, provisioning of resources toward kin) (Stearns 1992). Due to the finite nature of such resources, organisms are often forced to make trade-offs to allocate their resources in the most "optimal" way in their current environment, leading to suites of coadapted traits.

Classical conceptualization of life history strategies predicts that organisms will fall generally into one of two categories: *fast* and *slow* life history strategies (e.g., Stearns 1992). Organisms that pursue a fast life history strategy will typically come to reproductive age earlier, have a shorter life span, and emphasize bearing many offspring with limited parental investment. Slow life history strategies entail the opposite – that is, coming to reproductive age more slowly, having a longer life span, and having greater parental investment in fewer offspring. In sum, LHT predicts that organisms pursuing a fast life history strategy will favor resource allocation toward reproductive efforts, while organisms that pursue a slow life history strategy will favor resource allocation toward continued growth and maintenance; both are seen as viable strategies that

ultimately facilitate survival till reproduction. Through the lens of LHT, suites of coevolved personality traits can be understood as adaptive strategies to increase reproductive success (and consequently evolutionary fitness) under the organism's current environmental context. Traits that are related to life history domains tend to vary together, and these may organize generally into the fast and slow life history strategies, with the goal of calibrating organisms to best fit their environments.

Different types of environments favor the adoption of different life history strategies. In unpredictable environments with high mortality rates, the environment may favor organisms that are less inclined toward future planning. While future planning may be adaptive in stable and predictable environments, this strategy may lead to costs such as missing out on mating opportunities. Along these lines, LHT predicts that fast life history strategies will be related to personality structures that are associated with less prosocial motivations and behaviors since reliance on social rules and connections is most often a long-term investment strategy (Frank 1988).

Traits that cluster together to resemble a slow life history strategy, such as positive relationship attributes and attachment, are negatively correlated with traits that cluster together to resemble a fast life history strategy, such as Machiavellianism and risk-taking (see Gladden et al. 2009 for review). Similarly, Figueredo and colleagues (2007) found empirical support for the relationship between life history strategies and personality structure. Multiple traits that were related to life history domains, such as future planning, quality of parent's relationship, social support, attachment to romantic partners, and prosocial behavior, clustered together. These traits are related to a slow life history strategy because they emphasize investing resources in the future, rather than in short-term gains. Although this fast-slow dichotomy is useful in conceptualizing these distinct strategies, it should be noted that it may be more realistically viewed as a fast-slow continuum. Regardless, the clustering of specific individual differences across this fast-slow continuum

tends to give rise to particular personality traits (see Table 2). The following section discusses how these personality clusters were revealed to researchers, and how personality models have since been constructed and utilized.

Psychometrics of Personality Measures

Most personality measures are created using one of two approaches. The first involves the creation and administration of questions or items to a large sample to determine the validity of the measure (i.e., is the measure actually measuring what it is believed to measure?) (Myers et al. 1985). The second and more prominent method is the lexical approach (e.g., Lee and Ashton 2004). Researchers who utilize this method compile various personality-related adjectives. These adjectives are then rated by a large number of people responding about themselves (self-report) or others (observer-report). These ratings are then statistically analyzed using factor analysis to generate clusters of personality adjectives (e.g., shyness and lower talkativeness may be grouped together in a factor analysis). These clusters are finally named as various personality traits (e.g., introversion). Many prominent personality measures, including the Big Five Model (Costa and McCrae 1992) and the HEXACO Personality Inventory (Lee and Ashton 2004), were created using this method.

The Big Five Model

Within the Big Five Model (also called the five-factor model; Costa and McCrae 1992), each of the five personality factors (i.e., Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism) has distinct motivational and behavioral tendencies. From the perspective of evolutionary personality psychology, the "optimal" level of each trait is dependent on the environmental context.

Individuals who are high in the Big Five factor Openness to Experience are inventive and curious

and demonstrate an appreciation for artistic and intellectual endeavors (Costa and McCrae 1992). High levels of Openness to Experience have been associated with both positive (i.e., artistic creativity and intelligence) and negative (i.e., proneness to supernatural beliefs, schizotypal personality disorder, and psychosis) outcomes. As such, depending on the environment, high levels of Openness to Experience may be beneficial or detrimental (Nettle 2010).

Individuals who are high in the Big Five factor Conscientiousness are organized, dutiful, and disciplined, and make long-term plans and goals (Costa and McCrae 1992). As such, high levels of conscientiousness are particularly advantageous in a modern environment that emphasizes productivity. High levels of Conscientiousness are also related to rigidity and inflexibility. Thus, in an unpredictable environment, high levels of this trait may be costly if it limits an individual's capacity to react appropriately on short notice (Nettle 2010).

Individuals who are high in the Big Five factor Extraversion are outgoing, energetic, social, and stimulation-seeking (Costa and McCrae 1992). Such individuals typically have more sexual partners and more social status and are more physically active. The fitness benefits of such traits are obvious, as they take advantage of the highly social nature of human beings. Indeed, these characteristics are most adaptive in novel environments with fluid group structures, as individuals high in Extraversion will successfully influence the group and attain multiple mates. However, in environments where the dominance hierarchy is very stable, being gregarious and charismatic may be a costly strategy (Nettle 2010).

Individuals who are high in the Big Five factor Agreeableness are friendly, compassionate, trusting, and helpful (Costa and McCrae 1992). Such individuals are highly cooperative and will seek out joint connections and interpersonal relationships. Like Extraversion, high levels of Agreeableness also take advantage of the social nature of humans. However, low levels of Agreeableness may be beneficial if an individual exists in a population that is high in Agreeableness, as it provides the opportunity to exploit other individuals (Buss and Duntley 2008).

Finally, individuals who are high in the Big Five factor Neuroticism are less resilient to stress, are at a higher risk of mental illness, have difficulties in interpersonal relationships, and may experience significant negative affect (Costa and McCrae 1992). However, negative emotional states such as these are useful in environments where high sensitivity to threat is necessary for survival. For example, women are generally higher in this trait than men, and it is thought to reflect the adaptive nature of high threat detection when reproductive success is so costly (i.e., costs associated with carrying, delivering, and rearing offspring; Nettle 2010).

The HEXACO Model

The HEXACO model is a contemporary model that provides advantages such as strong cross-cultural validity and an explicit evolutionarily informed theoretical foundation (Lee and Ashton 2004). The HEXACO model includes six personality factors, each of which can be further broken down into four facets. The HEXACO model arose from a lexical database that included data from individuals in multiple cultural contexts, such as Korea, Italy, Poland, and a French-speaking part of Canada (Ashton and Lee 2007). By expanding their lexical data to include different cultures, they were able to identify a sixth trait called Honesty-Humility. Additionally, the HEXACO factors Emotionality and Agreeableness differ substantially from the analogous and respective Big Five factors Neuroticism and Agreeableness. A major difference in these constructs is the HEXACO's emphasis on capturing evolutionarily relevant kin-altruistic tendencies in crafting Emotionality and Agreeableness (as well as Honesty-Humility), whereas the Big Five Neuroticism and Agreeableness did not have this same objective. Furthermore, while the HEXACO facets Extraversion, Conscientiousness, and Openness to Experience share a name with factors in the five-factor model, they have notable differences in their definitions (see Table 1 for factor descriptions).

The traits in the HEXACO model can be interpreted as related to one of two adaptive

Evolutionary Personality Psychology, Table 1 Descriptions of the HEXACO personality factors

Function	Factor name	Facets	Description
Engagement and endeavor	Extraversion	Social self-esteem	High levels of Extraversion indicate self-confidence, enjoyment of social gatherings, feelings of enthusiasm, and energy. Low levels indicate feelings of awkwardness in social settings, indifference to social activities, and less optimism and liveliness
		Social boldness	
		Sociability	
		Liveliness	
	Conscientiousness	Organization	High levels of Conscientiousness indicate orderliness, attention to detail, dutifulness, and long-term planning and goal setting. Low levels indicate disorderliness, disorganization, and limited self-regulation
		Diligence	
		Perfectionism	
		Prudence	
	Openness to Experience	Aesthetic appreciation	High levels of Openness to Experience indicate aesthetic appreciation, interest in radical ideas, imaginativeness, and inquisitiveness. Low levels indicated limited curiosity and creativity and limited interest in art and novel ideas
		Inquisitiveness	
		Creativity	
		Unconventionality	
Altruism vs. antagonism	Honesty-Humility	Sincerity	High levels of Honesty-Humility indicate little interest in social status, avoidance of manipulation and exploitation, and modesty in terms of wealth. Low levels indicate willingness to exploit others for personal gain, an inclination to break rules, motivation from material wealth, and a sense of self-importance
		Fairness	
		Greed avoidance	
		Modesty	
	Emotionality	Fearfulness	High levels of Emotionality indicate fearfulness and anxiety, need for emotional support, empathy, and sentimentality. Low levels indicate limited concern of physical harm or stressful situations and emotional detachment from others
		Anxiety	
		Dependence	
		Sentimentality	
	Agreeableness	Forgivingness	High levels of Agreeableness indicate willingness to forgive others, leniency in judgments, willingness to cooperate with others, and limited anger. Low levels indicate a proneness to holding grudges, a propensity to be critical others, stubbornness, and higher levels of anger
		Gentleness	
		Flexibility	
		Patience	

Note: Information in this table from Ashton and Lee (2007). Visit www.hexaco.org for more information

functions: (1) endeavor and engagement-related functions or (2) altruism versus antagonism-related functions (Ashton and Lee 2007). Extraversion, Conscientiousness, and Openness to Experience describe one’s propensity to engage in, and allocate time and effort toward, social activities, task-related activities, and idea-related activities, respectively (Ashton and Lee 2007). An individual who is high in these three factors will be engaged, active, and invigorated, whereas an individual who is low in these three factors will be inert and passive (Ashton and Lee 2007). Depending on the environmental context, these traits may be beneficial or costly.

An individual who was high in the HEXACO factor Openness to Experience more interested in learning about one’s world may have had the advantage of possessing knowledge related to garnering resources which may aid in attracting mates. However, high levels of Openness to Experience may be costly. For example, the desire to explore new areas may impose some risks to physical health. Similarly, individuals who were high in Conscientiousness would have had energetic costs due to the propensity to engage in more tasks, some of which would have involved physical labor, but also the energetic costs of self-regulation and inhibiting one’s impulses. Conversely, in more modern environments, the

foresight and productivity associated with high levels of Conscientiousness may be adaptive. Individuals with high levels of Extraversion would have had similar energetic costs due to being lively and sociable. However, higher levels of Extraversion may have also afforded an individual a larger social network, and the advantage of having more options for allies and mates (Ashton and Lee 2007).

More specifically, the HEXACO factors Honesty-Humility, Emotionality, and Agreeableness each represent an individual's tendency to be altruistic or antagonistic. Honesty-Humility and Agreeableness are thought to be indices of an individual's orientation toward reciprocal altruism. While Honesty-Humility is a marker of an individual's willingness to exploit others (or avoid exploiting others) for personal gain, Agreeableness measures an individual's willingness to forgive or be exploited by others (Ashton and Lee 2007). High levels of this trait offer the important benefit of receiving reciprocal cooperation from others through the demonstration of mutual respect and trust. However, the cost of being high in Honesty-Humility is missed opportunities for personal gain that individuals who are low in Honesty-Humility will readily seize. Individuals who are high in Agreeableness may incur the cost of being taken advantage of by individuals who are low in Honesty-Humility, as they tend to be more lenient in their judgments of others and are prone to being cooperative. However, this cooperativeness also grants adaptive benefits as individuals with high Agreeableness will benefit from continued and reciprocal cooperation from others. Emotionality is hypothesized to be uniquely related to an individual's orientation toward kin altruism and self-preservation (Ashton and Lee 2007). Individuals who are high in Emotionality will avoid physical danger and the related costs, thus negating much of the harm that may fall on themselves or their kin. High Emotionality is also associated with the development of separation anxiety disorder and phobias, due to the high degree of dependence, sentimentality, fearfulness, and anxiety that characterize high levels of this trait (Ashton and Lee 2007).

Despite the differences in these personality models, certain clusters of personality traits seem to emerge that may represent "optimal" responses to specific environmental cues as per LHT. Key to an evolutionary view is seeking an understanding between the observable characteristics of an organism (its phenotype) and its genetic code (its genotype). Thus, an evolutionary personality psychology view requires a consideration of the putative genetics underlying the phenotypic and observed personality clusters of these dominant models of personality (Table 2).

Genes and Personality

Personality, like other complex traits, is polygenic. That is, personality traits are influenced by a combination of genes (Plomin et al. 1994). As such, there are multiple factors at the genetic level that may influence the variation in genes that may consequently influence personality traits. The genetic influences of personality traits are typically evaluated by comparing the traits that are similar across individuals that share both genetic material and their environment, such as identical versus fraternal twins. These studies suggest that almost all aspects of personality traits are, at least in part, heritable (Plomin et al. 1994). More specifically, various adoption, twin, and family studies have demonstrated significant similarities in personality traits between close genetic relatives and fewer similarities between more distant genetic relatives. For example, one study showed that the average correlation between monozygotic twins was 0.55, compared to -0.07 for dizygotic twins (Plomin et al. 1994).

Additionally, environmental influences are also equally powerful in shaping one's personality traits (Van Gestel and Van Broeckhoven 2003). For example, antisocial personality and its associated behavior is, in part, influenced by the interaction between childhood maltreatment and the monoamine oxidase A gene (Caspi et al. 2002). Similarly, researchers have demonstrated that aggressive and competitive environments have

Evolutionary Personality Psychology, Table 2 Life history strategies and associated personality traits

Life history strategy	Observed personality traits	Survival and reproductive value
Slow life history strategies	Big Five:	Outgoing and adventurous to meet and attract mates Open to new ideas and experiences with others
	Extraversion	
	Openness	
	Conscientiousness	
	Agreeableness	
	Low Neuroticism	
	HEXACO:	Uphold the rules of the group Cooperate with others
	Honesty-Humility	
	Extraversion	
	Agreeableness	
	Conscientiousness	
Fast life history strategies	Big Five:	Cooperate as long as it takes to get the resources needed to survive/reproduce
	Low Agreeableness	
	HEXACO:	
	Low Honesty-Humility	More mating compared to parenting effort Bully others to get resources
	Dark Triad:	
	Narcissism	
	Psychopathy	
	Machiavellianism	

Note: Information in this table from Ashton and Lee (2007), Figueredo et al. (2007), Gladden et al. (2009), and Manson (2016). Visit hexaco.org for more information

significant effects in changing an individual’s testosterone levels and consequently their aggressive behaviors (Archer 1991). These examples support the importance of calibration of an organisms’ genetic composition/predisposition as well as environmental pressures in shaping personality traits and associated behaviors. More specifically, both the genetic predispositions and environmental contexts may be important correlates that help us to understand the link between personality and various behaviors. The genetic profile within everyone prepares individuals to respond to their environment with either or both prosocial strategies and antisocial strategies in the service of survival and reproduction.

Personality and Prosocial Behavior

Prosocial behavior is defined as overt, voluntary action intended to benefit others (Batson 1998).

Prosocial behavior may have proven especially beneficial in early human environments characterized by unpredictable climate, food supply, and the threat of competing tribes (Simpson and Beckes 2010). Considering the division of labor among early humans, which involved different members taking responsibility for such important tasks as hunting, gathering, child care, and security, it would have been beneficial to the group’s survival to work cooperatively to collectively reap the benefits.

More specifically, prosocial behavior that helps propagate one’s genes through acts directed toward genetic relatives may be the most obvious illustration of its adaptive quality. Indeed, humans demonstrate extensive prosocial networks among genetically unrelated individuals in addition to their kin. One theoretical explanation, the Cooperative Breeding Hypothesis, describes a social system characterized by alloparental care, in which individuals take on caregiving roles toward non-descendants. Cooperative breeding therefore

facilitates the formation of family units, systems in which prosocial acts are even more beneficial to the actor. In other words, prosociality toward kin benefits the survival of genes in related organisms (Hrdy 2007).

According to the HEXACO model, prosociality is most closely linked with the trait Honesty-Humility. This is illustrated, for example, by individuals who are high in Honesty-Humility demonstrating an increased tendency to actively cooperate and engage in pro-environmental behavior (Ashton and Lee 2007). While the research emphasizes Honesty-Humility as an important trait in relation to prosocial personality, there are other personality traits that may account for specific prosocial tendencies. This is illustrated within the HEXACO model by the interstitial scale of Altruism versus Antagonism, a representation of a blend between Honesty-Humility, Agreeableness, and Emotionality. High scorers on these domains tend to be sympathetic toward others and react with generosity to those in need of help, indicating that being high on these facets may be related to increased prosociality (Ashton et al. 2014). A specific example may be in the context of relationships in which individuals score highly on the sentimentality facet of Emotionality, associated with the development and maintenance of strong emotional bonds, as they may be more inclined to behave prosocially (Ashton et al. 2014). This may unfold in the context of familial relationships, such as the parent-child or within extrafamilial contexts, and between members of the same in-group. These findings generally suggest that prosocial tendencies may have clearer links with living a slow life history strategy as opposed to a fast one since inherent in this orientation is reciprocity, a forward-thinking behavior that relies on continual interactions between individuals.

There is little doubt that as an obligate social species with cooperativeness as one of its hallmark traits, humans have been selected to manifest prosocial traits and behaviors. However, within any social system lies the possibility for the emergence of exploitation and cheaters. Hence, we must also consider the potential adaptive benefit of non-prosocial individuals.

Personality and Antisocial Behavior

Descriptions of personality traits tend to revolve around thinking, feeling, and behaving in social situations, but not all encounters have positive social intentions. This points to the existence of personality traits and styles geared toward deception, self-enhancement, aggression, and callousness toward others, suggesting the presence of attributes with more negative social intentions. These types of personality traits have been described as *dark personalities*. The most prevalent model of dark personalities is the Dark Triad model developed by Paulhus and Williams (2002), which includes the personality dimensions narcissism, Machiavellianism, and psychopathy.

Narcissism is a personality construct that emerged from the clinical conceptualization of individuals preoccupied with their own self-image, social status, and personal dominance (Furnham et al. 2013). It owes its name to the ancient Greek story of Narcissus, a hunter that fell in love with his own reflection upon seeing it in the water, thereafter being unsatisfied with the love and connection felt with others. Machiavellianism describes a personality that has interpersonal manipulation at the core of its manifestation, along with characteristics of distrust of social rules and morals and a cynical and pessimistic attitude about life (Furnham et al. 2013). The construct owes its name to the political thinker Niccolò Machiavelli, who lived in sixteenth-century Florence, Italy. His book *The Prince* was written as a guide to attaining political and economic power using unprincipled methods of deception and manipulation. Lastly, psychopathy is a personality construct that also came from clinical observations of chronically difficult and enigmatic patients who exhibited marked and reduced emotional affect, interpersonal charm and grandiosity, and disinhibited and sensation-seeking attitudes (Furnham et al. 2013). These individuals often come in contact with the law or engage in behavior that would constitute versatile illegal or criminal conduct such as fraud, assault, and sexual coercion (Hare 2003).

What makes these personalities “dark” and others not? One proposed idea has been that

these traits each have a callousness at their core in how they deal with other people (Paulhus and Williams 2002). From this perspective, the motivations and behaviors of individuals who are unbothered by committing callous, harsh, and aggressive acts against others constitute darkness of personality. This has led some researchers to consider the personality construct of everyday sadism to also be considered a dark personality, creating four constructs that make up the Dark Tetrad. A second idea comes from empirical observations that these personalities all covary with lower levels of the Big Five factor Agreeableness (Furnham et al. 2013). The aspects of lower Agreeableness on the Big Five factor suggest that Dark Triad personalities are immodest, non-compliant, untrusting, less altruistic, not straightforward, and lacking tender-mindedness. A third idea uses the HEXACO model of personality, particularly the Honesty-Humility factor of this model (Hodson et al. 2018). From this perspective, what makes dark personalities “dark” is their covariance with Honesty-Humility, which captures sincerity, modesty, fairness, and greed avoidance (Lee and Ashton 2004).

From an evolutionary personality psychology view, these three attempts to understand dark personalities and its associated antisociality all represent attempts to locate where in personality antisocial tendencies comes from. Focusing on antisocial behavior instead of dark personalities, lower Honesty-Humility appears to be associated with aggression and bullying (e.g., Book et al. 2012). Moreover, individuals who are lower in the HEXACO factor Agreeableness may also be more likely to engage in aggressive or uncivil behavior, as these individuals have a propensity to be uncooperative with others and are more likely to respond to negative situations with anger. Dinić and Wertag (2018) found that while lower Agreeableness was the strongest predictor of aggressive behavior, lower Honesty-Humility and lower Emotionality (in females) were also significant predictors of aggressive behavior, emphasizing the importance of studying these complex personality profiles. Further, from an adaptive perspective, it is important to consider that there are not only various costs and benefits to

higher and lower levels of each trait but also costs and benefits to engaging in different types of antisocial behavior.

How might we view dark personalities when considering a more ultimate, less proximate, view of human behavior and personality in using the tools afforded by an evolutionary perspective? Most perspectives have emphasized a life history framework for understanding dark personalities, placing them in the category of fast life history strategies that are geared toward mating and away from parenting (Furnham et al. 2013). The pattern of men consistently scoring higher on all three dark personality traits compared to women (Muris et al. 2017) provides some evidence for this claim, since males are more likely to be faced with the adaptive problem of access to mates, making their reproductive success more skewed than females, and subsequently selecting for more mating-focused personality styles (see section “Sex Differences in Personality”). Another evolutionary-informed view of the dark personalities takes into consideration their unprincipled lack of social orientation. This can be described as investing time and energy in agency and the self at the expense of community and others, or in manipulation and deception at the expense of commitment and transparency.

Acknowledgment of humans as an obligate social species does not necessitate that all humans engage in prosocial acts. Quite conversely, the fundamental dependence humans have placed on each other in creating a social realm guarantees the existence of social rules and expectations that themselves can be relied upon for exploitation and self-gain (Buss and Duntley 2008). Dark personalities may be one example of social rules and expectations among human groups having selected for exploitative and self-oriented individuals, if those strategies indeed had some reproductive payoff. For example, Honesty-Humility (and Agreeableness from the Big Five) tends to be normally distributed in populations. This suggests that human history may have been colored by both prosocial and exploitative personalities. An evolutionary personality perspective can conceptualize dark personalities in a nonarbitrary way (Buss 2009), potentially connecting their very origin

and emergence to the origin of human social groups. This view challenges non-evolutionary perspectives of “darker” personality styles as pathological (i.e., narcissism and psychopathy, including other personality constructs such as Borderline Personality Disorder and Histrionic Personality Disorder). Instead of viewing these as somehow pathological, an evolutionary personality perspective forces consideration of how these personality styles reflect traits and behaviors that underlie a response of organisms to specific environmental pressures to ensure their survival and reproduction.

Sex Differences in Personality

A benefit in using an evolutionary perspective of personality is that it affords a nonarbitrary formulation and appreciation of the connection between organism and its environment (Buss 2009). In other words, organisms manifest specific traits that help “match” them to a particular environment, ensuring survival and reproduction. Since reproduction is funneled and constrained by the fusion of gametes (i.e., sperm in males and eggs, or ova, in females), a fundamental part of this decision would be identifying one’s biological sex and planning a strategy accordingly. According to traditional notions of the evolution of traits and the sexes, females incur more of the costs of reproductive investment (both gestating and parenting), which includes having to wait a necessary period before having more offspring (e.g., at least 9 months for humans), and thus have been selected as the choosier sex. Males, on the other hand, are not limited in their reproductive capacity since the amount of reproductive effort can be as short as a few seconds (i.e., insemination). Thus, males may have faced more selection pressures to exhibit a more mating-focused strategy compared to a more parenting-focused strategy of females. This is not to say that females cannot be mating-focused or that males are not parenting-focused; it is simply to acknowledge that selection pressures can act on each of these reproductively constrained sexes to create different viable strategies for having one’s genes

propagated into the next generation. Individuals of each sex diverging too far from the “optimal” level of thinking and behaving as a member of that sex would be subsequently selected against (Geary 2010). The resultant distributions of female-like and male-like personalities would represent the varying viable strategies for acquiring mates, reproducing, and raising healthy offspring that themselves can reproduce.

Based on this evolutionary logic, it is expected that both personality similarities and differences should exist among the sexes (Geary 2010). Similarities between the sexes should be strongly rooted in the existence and maintenance of a cohesive and functioning social group (see section “[Personality and Prosocial Behavior](#)”). Both sexes share an interest in the well-being of the members of their social group, especially closely related kin. As a social-dependent species, humans require the guarantee of social cooperation, mutual dependence, and partitioning of labor into distinct tasks and groups. It is no wonder, then, that normative personality traits have included socially relevant characteristics including communion, emotion-related traits (e.g., Neuroticism, Emotionality), trust-related traits (e.g., Agreeableness), honesty-related traits (e.g., Honesty-Humility), and work-related traits (e.g., Conscientiousness). The existence of these personality traits reflects selection pressures acting on a social species, and both sexes should exhibit minimum threshold and possibly equal levels of these traits (Geary 2010).

However, some differences are expected between the sexes as well, which may represent the specialization of two major sex-biased pathways that have emerged and contribute to the social welfare of the group: those of warriors and worriers (Benenson 2014). These differences characterize boys and men as warriors, and girls and women as worriers based on defined sex-specific adaptive problems of surviving and reproducing. As warriors, tasks of developing individual skills and ensuring group security foster a need for emotional strength and resilience as well as a preoccupation with specializing in a particular niche to contribute to the group. As worriers, the prime task of caring for and raising the young of the group fosters a dependence on

keen social navigation skills, emotional understanding, and acceptance that can ensure survival of offspring through extended care and support from the social group. Interspersed within this framework exists the selection pressures of sexual selection, including both intrasexual competition and intersexual mate choice (Geary 2010). Intrasexual competition, especially among males due to the higher variance in reproductive success, can create environments where competition for access to mates may select for more disagreeable, hostile, and cheating personality traits in an effort to oust the mate competition. Intersexual mate choice, on the other hand, can select for particular personality traits (e.g., risk-taking) in the opposite sex that may not be as desirable to the other sex. Either way, these selection pressures can create sex differences in the personality and individual differences we see in humans.

Sex differences in personality traits can be confounded by variables such as age, culture, and historical context. Still, empirical research regarding sex-based personality differences often produces complex and controversial results. Research that utilizes the HEXACO model has suggested that females report a higher mean level of Emotionality-related traits than males (Ashton and Lee 2007). For the Dark Triad traits, meta-analyses suggest that males score significantly higher than females on all three traits, most notably on psychopathy (Muris et al. 2017). That these traits may capture more of a mating-focused personality (e.g., Furnham et al. 2013) is in line with their male-biased manifestation. While there are significant and well-documented differences between the sexes in terms of personality traits, there appears to be some commonality in the ways that these traits change as individuals mature and grow older.

Personality Throughout the Life Span

Although personality traits are often believed to be stable, there is evidence that personality changes in specific ways throughout the life span, particularly from adolescence into adulthood (e.g., McCrae 2010). Cross-cultural data

that utilizes the Big Five model has demonstrated a tendency to decline in the traits of Openness, Extraversion, and Neuroticism and increase in Agreeableness and Conscientiousness over this period of development (e.g., McCrae 2010). It appears that as people mature, they tend to be able to forgive more easily, are more willing to cooperate with others, and generally become more organized and focused on their goals. Increases in these traits may be indicative of individuals learning from their previous experiences in a way that modifies their traits through their life experience and changing environmental context. This highlights the modest plasticity of personality over the life span due to environmental influence and further demonstrates the developmental adaptability of personality. Therefore, the change in these traits may be an adaptive strategy for individuals to cooperate more with others as they move to adulthood and become more independent members of society, as well as to attain their goals.

Moreover, longitudinal research examining personality traits across the life span suggests that trait stability increases as individuals age (e.g., Roberts and DelVecchio 2000). That is, individual personality traits are more likely to change earlier on in development and change less as individuals get older, which is supported by LHT predictions that early-life calibration sets the stage for one's traits and behaviors, with plasticity becoming rarer as individuals age and developmental windows close.

Conclusion

In this entry, we have sought to demonstrate broadly the usefulness that an evolutionary personality psychology perspective provides for understanding some of the individual differences in behavior (e.g., prosocial, antisocial) and personality that we see in humans. Its primary strength is in providing a nonarbitrary conceptualizing of individual differences and showing how personality and other individual difference traits may represent gene-environment calibrations that have emerged within humans through many generations of selection.

Definition

The evolutionary perspective is a contemporary approach originating from Darwin's theory of natural selection and endorsing the interactionist paradigm by considering the roles of genes and the environment as the sources of behavior.

Introduction

All modern evolutionary approaches are based on Charles Darwin's theory of natural selection (Buss 2012). According to this view in evolutionary biology, biological properties often have adaptive functions (i.e., adaptation), while they may also emerge as a by-product of some other adaptation. It could also be that a random product came out completely by chance. For example, the umbilical cord is adaptive because it provides the exchange of nutrients between the placenta and the embryo. The belly button is the by-product of this adaptation. The shape of the belly button varies from person to person, so it is a random product.

The evolutionary approach in behavioral sciences (i.e., evolutionary psychology) derives from the assumption that higher cognitive functions such as intelligence, analytical thinking, language, or empathy are either adaptations or by-products of other adaptations (Confer et al. 2010). In other words, evolutionary psychology claims that, like biological organs, certain mental traits are transmitted to the next generations as a result of natural selection, because many of these psychological mechanisms are adaptations that have emerged as long-term solutions to problems related to survival or reproduction. Having emerged in psychology, this perspective can be applied more generally: to all subfields of psychology and to many nearby disciplines (i.e., political sciences, economics) and to many ancient philosophical debates such as the origins of morality and religious belief, language, and intelligence. For example, there are approaches arguing that belief in God is an adaptation on its own (Johnson 2015) or a by-product of a higher-level adaptation (i.e., the theory of mind, Boyer 2001). There are also theoretical approaches proposing that our moral sense emerged due to having adaptive features (i.e., Haidt 2012).

However, the main problem of evolutionary approaches is the lack of consensus about what to categorize as an adaptation. Particularly in the field of evolutionary psychology, this ambiguity is extreme, because having a genetic basis is often seen to be a condition for labeling a trait as an adaptation. But this condition by itself is not sufficient since, for example, adaptations (other than gender-specific) must be prevalent across the species. Adaptations do not have to be innate, but they must at least occur during the development process. The most important feature of the adaptations is that it should solve a problem in the past environment in an efficient and economical way. For example, there is some evidence suggesting that moral sensitivity in general, religious belief in particular, serves functions in terms of promoting large-scale cooperation among humans.

In addition, there are two different levels of explanation in the evolutionary approach. The first is the ultimate explanation that reveals the

evolutionary origins of behavior (explaining why and how it came about) and revealing its brain foundations. For example, it is a kind of ultimate explanation to say that the evolutionary function of the human language is to promote large-scale cooperation commonly seen in human societies. The other is the proximate explanation and is concerned with the psychological meaning of behavior. For example, stating that the reason why we help our relatives more than others is due to feeling emotional closeness to them is a kind of proximate explanation.

Evolutionary psychology relies on an interactionist paradigm. In other words, behavior and underlying mental processes cannot be explained completely either by genetics or by environmental factors. The emergence of behavior depends on a combination of these two. For example, there are approaches arguing that people have a biological potential to acquire language (Hauser et al. 2002). Even though the capacity for language is a genetically acquired evolutionary trait, when this biological potential does not interact with environmental stimuli (i.e., speech of others), one will not develop advanced language skills. Therefore, the evolutionary approach endorses the interactionist paradigm by considering the roles of genes and the environment when explaining behavior.

[Sexual assault](#)

Definition

The use of force or threat of force to achieve penile-vaginal penetration of a woman without her consent (Kilpatrick et al. 1992; Thornhill and Palmer 2000).

Introduction

When sociologists and clinical psychologists look at rape, they look at certain variables and outcomes, such as how victims are affected, what kind of psychological impact does the victim experience, and what factors could have been changed that may have affected the outcome. Evolutionary psychologists have attempted to explain why perpetrators engage in rape. This entry will outline major evolutionary psychological theories and perspectives regarding why rape occurs. Because the majority of rapes are perpetrated by men (Black et al. 2011), this entry will focus on evolutionary psychological research focusing on male perpetrators.

The Five Types of Rapists

As proposed by McKibbin et al. (2008), male rapists can be divided into five categories. These five types of rapists are (1) the specialized rapist, (2) the disadvantaged male, (3) the opportunistic rapist, (4) partner rapists, and (5) the high-mating-effort rapist. Using an evolutionary perspective,

we will also examine the mechanisms that motivate these males to engage in rape.

The Specialized Rapist

Perpetrators of this category often fit a certain criterion in which they are sexually aroused by violent stimuli (McKibbin et al. 2008).

Since this particular perpetrator is the most common that people think about, we can now look at the topic of insemination. Thornhill and Palmer (2000) hypothesized that these specialized rapists have a developed or evolved mechanism that makes them more likely to rape a highly fertile woman versus a woman who is less fertile. With that being said, it is still unclear if this is truly a mechanism specific to rapists or if this is a trait that is shared by all men as a mating strategy. Another adaptive outlook proposed that what these rapists may have is the ability to produce large amounts of semen which, when ejaculated into a woman during rape, would increase the chance of inseminating that woman. This would support the claim that rapists perform this act in the effort to pass on their genes.

The Disadvantaged Male

Perpetrators of this category normally feel disadvantaged some way that what they feel make them unworthy or unable to find a long-term mate. These disadvantages can range and vary widely, but some examples would include being impotent, some sort of physical disfigurement, social awkwardness, etc. Evolutionary perspectives on the perceived non-attractiveness these males feel, or experience, deal with poor facial symmetry, which is perceived as less desirable by potential mates (Gangestad and Thornhill 1999). When these males feel as though they will never find a mate, they turn to other measures, such as rape, in order to pass along their genes and produce offspring (see above).

The Opportunistic Rapist

Opportunistic rapists are men who use rape or sexual coercion in instances when the backlash (associated costs) that is normally associated with rape is low. This includes retaliation by victims and the victims' families or societal prosecution

and/or persecution (McKibbin et al. 2008). Gottschall (2004) explains that instances of rape actually increase during times of war, and this is attributed to the opportunistic rapist because men at war are subject to little or no backlash from crime.

Partner Rapists

Perpetrators of this category engage in what is known as partner rape. These perpetrators already have a long-term mate but feel the need to force themselves upon their mate against his/her wishes. This is believed to be a response to stimuli which are triggered when the male believes his partner has engaged in unfaithfulness. This often leads him to establish dominance. A mechanism associated with this is what's known as kamikaze sperm (Baker and Bellis 1988). These are sperm that are specifically tasked with locating competitive sperm inside the vaginal canal and then destroying the rival sperm. Another mechanism viewed is that when the mate suspects unfaithfulness, the male will produce excess amounts of sperm in order to flush out any competitor sperm (Thornhill and Palmer 2000).

The High-Mating-Effort Rapist

Males within this category are not socially awkward, and they are not disadvantaged; they are, in fact, more sexually active and more attractive than almost all other rapist subsets. Lalumière et al. (2005) hypothesized that males of this category are often aggressive and dominant and have a high amount of self-esteem, concluding that these rapists display many psychopathic traits. Lalumière et al. (2005) also noted that these males primarily use typical mating strategies to produce a high number of mates but then will turn to rape and sexual assault when conventional means fail them.

Effects on Females

Defense Mechanisms

Davis and Gallup (2006) noted in their research that women may have defense mechanisms that would protect them from the costs that would come with being raped. They proposed that

preeclampsia, miscarriages, and spontaneous abortion are adaptive responses by the female body to terminate pregnancies that are not in the women's best interests, whether that be health or reproductive related. This adaptation is being associated with rape because there is a higher rate of those occurring with victims of rape. Smuts (1992) proposed that women make more alliances with groups of men to protect themselves from rapists. Wilson and Mesnick (1997) call this *The Bodyguard Effect* which says that women's mating preferences lean more toward physically and socially dominating males in order to deter possible dangers like abuse, assault, and rape.

Emotional and Societal Effects

Perilloux et al. (2012) point out that when women become victims of rape, they retain feelings of rage, fear, humiliation, and shame. This often leads to the development of various clinical issues such as depression, anxiety, sexual dysfunction, and PTSD. An evolutionary perspective on the effects of rape could be beneficial to research because a key feature of women's mating strategies is their evolved perceptions of viable romantic and sexual partners. Rape impedes those evolved mechanisms and could possibly lead women to lose out on potential long-term mates due to the psychological costs of rape.

Perilloux et al. (2012) conducted an experiment in which they looked at two groups, "victims of completed sexual assault" and "victims of attempted sexual assault." Researchers measured a host of variables which consisted of health, self-esteem, self-perceived attractiveness, self-perceived value as a romantic partner, family relationships, work life, social life, social reputation, desire to have sex, frequency of sex, enjoyment of sex, and long-term committed relationships. What was discovered was that 11 of the 13 domains analyzed showed a statistically significant impact on "victims of completed sexual assault" livelihood. The largest effect size was seen in self-esteem, self-perceived value as a romantic partner, and sexual reputation. The two domains that did not differ between groups was work life and enjoyment of sex. Based on results of the experiment, researchers see a strengthened argument, in

an evolutionary psychological and fitness point-of-view, on how rape and/or sexual assault is so costly and how rape plays a key role in victims' mating strategies and mating outcomes.

Conclusion

Looking back on the evidence that has been pulled together by researchers around the world in various fields of psychology, there are a couple of statements that show a lot of proof and are represented by the research. Firstly, we can break the term rapist into different subsets of the term depending on hunting strategies, preference, and thought processes. Evolutionary speaking, these subsets of rapists could lead us to further research in which we identify evolutionary or adaptive mechanisms that would explain formations of the cognitive processes that would form and lead to the blooming of a rapist.

Secondly, there is research out there that suggests that women have certain mechanisms cognitively that would allow them to protect themselves from would-be rapists and/or unwanted offspring that would come about from being raped. Evolutionarily speaking, these mechanisms would protect oneself from harm as well as keep the woman from harm, both mentally and physically.

Lastly, victims of rape can be affected in a variety of ways. Oftentimes, however, the repercussions and costs that are experienced by victims of sexual assault differ from the costs and repercussions that a victim of attempted sexual assault would experience. These repercussions affect all sorts of domains such as how enjoyable sex is to self-perceived value as a romantic partner. These costs could lead to a decline in a woman having offspring, which in turn prevents genes from being passed on, ultimately falling into the "survival of the fittest" category that do not survive.

Further research is required to really delve more into all these proposals. There are plenty of avenues that researchers can take in order to test more on the evolutionary perspectives of rape, and these hypotheses can have an impact on other areas of psychology as well.

[Evolution of religion](#)

Definition

How and *why* are the two different questions to examine the evolution of religions. The first question requires taking a sociohistorical (and perhaps also a phylogenetic) perspective on religion and giving an exposition of the historical development of the phenomena collectively known as religion. The second requires taking a functional/adaptive perspective on religion and answering the thorny question of whether religion evolved as an adaptation or a by-product.

How Did Religion Evolve?

There is no consensus among scholars on the definition of religion. Some even argue that the concept of religion does not apply to all cultures and historical periods. For the present purposes, however, we will adopt Durkheim’s (1912) classic definition of religion as a set of beliefs and practices that unite groups into a moral community around a sense of the sacred. The “sacred” often, but not always, involves a supernatural realm with supernatural agents. Beliefs are mostly about the supernatural, whereas practices include rituals that aim to appease supernatural agents or to invoke their intervention in worldly affairs.

No nonhuman animal species display behavior that conforms to this definition of religion. We can

thus assume that full-blown religion is uniquely human. On the other hand, ritual-like behavior of elephants around the dead and mourning for the dead in several species have been observed. There is also suggestive evidence regarding Neanderthal burials, which might indicate belief in an afterlife. However, there is no conclusive evidence that religion existed before the advent of behavioral modernity.

The evolutionary history of religion in *Homo sapiens* has been most thoroughly described by the sociologist of religion Robert Bellah in his magisterial work *Religion in Human Evolution: From the Paleolithic to the Axial Age*. This section will follow his exposition.

Bellah (2011) describes three stages in the historical evolution of religion based on the evolution of representational abilities. The first is tribal religion which existed throughout the Paleolithic age. Following the psychologist Donald Merlin's (1991) classification, Bellah states that mimetic culture and enactive representations characterize this stage. The main form of religious practice is ritual, for which child play is the evolutionary precursor. Rituals enact social relationships, relationships to ancestors and to spirits and thus maintain the social order. Ritual burials with grave goods are first evidence of religious behavior which suggest belief in an afterlife. We still see tribal religion in modern hunter-gatherer societies.

In the next stage, we encounter archaic religion. This is the religious form of large agricultural societies. Mythic culture and symbolic representations (images and icons) characterize this stage. Religious concepts are communicated through visual art and oral narratives. Simple emotions are transformed into more specialized emotions and attitudes through symbolic representation: awe, equanimity, self-transcendence, etc. We first see the examples of this type of religion in ancient Mesopotamia, ancient Egypt, and Zhou China. The society is hierarchically organized and the god-king is the mediator between the national gods and the people.

In the final stage, we encounter Axial religion. Axial age is the name first given by Karl Jaspers (1949) to the period between 800 and 200 BC

(sometimes extended to cover the whole first millennium BC). This is the time when great religious traditions that still exist came into being almost simultaneously and with little contact among each other: Confucianism and Taoism in China; the Upanishads and Buddhism in India; teachings of the reformist prophets Isaiah and Jeremiah in ancient Israel; and those of Socrates and Plato in ancient Greece. What characterized this period was a quest for human meaning in the universe and the rise of an elite class of religious leaders and thinkers.

Theoretical culture and conceptual (standpoint free) representations characterize the Axial age. Religions develop a theology for the first time and they make a claim to be universal rather than just nationalist. Religion does not just serve to maintain status quo but criticizes and transforms it. Culture depends on writing and external storage of memory. The deity becomes transcendent and an ontological divide is introduced between God and humans.

Bellah maintains that, through this process of cultural evolution, new stages do not merely replace old ones but build upon them. Thus, theoretic culture is added to the already existing mimetic and mythic cultures. Interestingly, Bellah does not touch upon the two largest world religions today: Christianity and Islam. He thinks they are extensions of the classic Axial age religions and do not represent a new stage in the evolutionary history of religions.

Why Did Religion Evolve?

According to modern evolutionary theory, a trait that comes about as a result of the process of evolution has to be one of three things: an adaptation (the direct product of natural selection), a by-product (the nonadaptive vestige of another adaptation), or a random effect (not produced directly or indirectly by natural selection but the product of historical accidents; see Buss et al. 1998). Since religion is a highly complex and functional (in the nontechnical sense) phenomenon, we can rule out the possibility that it is an

accidental or random product of evolution. Thus, it either evolved because it somehow provided survival or reproductive advantage to ancient humans, or else it evolved as a side effect of other traits that did provide such an advantage. Accordingly, we can distinguish between religion as adaptation theories and religion as by-product theories.

Religion as an Adaptation

Adaptationist theories of religion generally emphasize the cooperative nature of religion: Religion promotes cooperation within a society. Large-scale cooperation between genetically unrelated individuals is usually seen as what makes humans unique among animals and what enables human civilization and is clearly adaptive. Since it is assumed that large-scale cooperation is unlikely to be brought about by standard evolutionary mechanisms (e.g., kin selection, direct or indirect reciprocity), religion is offered as the mechanism to do the job. If religion indeed promotes large-scale cooperation, it can be seen as an adaptation. Religion might play this role in several different but complementary ways.

One prominent aspect of many religions is the extravagant displays they employ: circumcision, fasting, snake handling, etc. One has to engage in these displays to be accepted and to remain in the religious group. One reason religion has defied an adaptationist analysis is that these displays are so costly, time consuming, and downright dangerous that they clearly decrease one's chances of survival. However,

The performance of these costly behaviors signals commitment and loyalty to the group and the beliefs of its members. Thus, trust is enhanced among group members, which enables them to minimize costly monitoring mechanisms that are otherwise necessary to overcome the free-rider problems that typically plague collective pursuits. (Sosis and Alcorta 2003, p. 267)

Thus, costly rituals engender trust among group members precisely because they are hard to fake by others who do not share the moral outlook of the group and only want to join the group to reap the benefits of group living without contributing anything. Trust, on the other hand, is

what enables cooperation among individuals who do not know each other personally (see also Bulbulia 2004; Henrich 2009).

Another way religion can promote cooperation and harmony in large groups is by invoking supernatural agents (traditionally referred to as gods) who are watchful, morally concerned and powerful. Noncooperators and other norm violators need to be monitored and deterred if intragroup cooperation is to be maintained. This becomes increasingly difficult to do on a personal basis as group size increases. If, on the other hand, everyone in the group believes in the existence of supernatural agents who watch and know about everyone, who are concerned with morally relevant behavior of group members, and who are powerful enough to punish norm violations wherever and whenever they occur, then norm violations can be effectively prevented. The so-called supernatural punishment hypothesis has been used to explain how religions with big moralizing gods can foster cooperation and vice versa: As religions expand at the expense of less successful forms of religion, their networks of cooperation also expand, and an ever-expanding large-scale cooperation is enabled (see Norenzayan 2013). The fact that participants who are reminded of a punishing God behave more altruistically to anonymous partners in an economic game (or hypothetically) is one type experimental support for the theory (Shariff and Norenzayan 2007; Yilmaz and Bahcekapili 2016). In addition, it has been observed that there is a negative correlation between belief in hell and national crime rates, whereas a positive correlation between belief in heaven and crime rate, again supporting the supernatural punishment hypothesis (Shariff and Rhemtulla 2012).

Religion as a By-product

Cognitive scientists of religion generally argue that religious thought is nothing special; general cognitive mechanisms that subserve belief formation produce religious beliefs under certain circumstances as well. Thus, religious thought is a by-product of ordinary thought, which has itself evolved as an adaptation.

Some of those general cognitive mechanisms include agency detection, theory of mind, and precautionary reasoning. Agency detection is the ability and tendency to detect the presence of agents that might cause harm to the individual. Theory of mind is the ability and tendency to attribute beliefs and desires to an agent and thus to predict the likely behavior of the agent. If these tendencies are extended to natural events without obvious explanations, one can deduce the existence of supernatural beings behind thunder, earthquakes, and the normal cycles of life, and thus take precautions to prevent or appease such beings. Religious belief and ritual can therefore be explained as a by-product without reference to a separate religious mental module or an adaptive function subserved by religion (see Boyer 2001).

If religious belief is a natural extension of ordinary cognitive processes, why do some individuals altogether lack such beliefs? An evolutionary psychology of religion should also be able to explain the evolution of irreligion. A recent attempt to do so argues that the same cognitive and cultural processes that lead to religiosity can also create a tendency toward atheism (Norenzayan and Gervais 2013). If theory-of-mind (or mentalizing) abilities create a disposition toward religious belief, individuals with weak mentalizing skills should be disposed toward religious disbelief. In fact, the autistic spectrum is associated with lower levels of belief in a personal God. Second, if religious belief is intuitive, individuals who routinely suppress intuitive thinking tendencies in order to think analytically should be disposed toward religious disbelief. In fact, scientists generally show much lower levels of religious belief compared to the general population. Third, if religious belief needs cultural support to be maintained, lack of public displays of religiosity should lead to irreligion. In fact, religious belief is especially low in secular societies where religious education and symbols have left the public sphere. Finally, if religious belief is a solution to existential needs such as security and control, individuals might be indifferent to religion if such needs are met by other means. In fact, religious belief is especially low in Scandinavian societies where social security systems are especially powerful.

Evolutionary Pressure on Meat Eating

Stanley Coren
University of British Columbia, Vancouver, BC,
Canada

Synonyms

Carnivorous, Flesh eating, Predacious,
Omniphagous

Definition

Factors influencing abandonment of herbivorous diet and favoring the inclusion of meat in a more omnivorous eating pattern.

Introduction

As far as we can tell the first primate appeared 65 million years ago, just about at the time that the dinosaurs had gone extinct together with over half of the world's other animal species. *Purgatorius* was a small animal who was an accomplished tree climber and looked much like a cross between a mouse and a squirrel. *Purgatorius* was also a vegan who took advantage of the fruits, flowers, and leaves which were now more abundant since the large herbivorous reptiles had disappeared from the planet. For millions of years, the descendants of *Purgatorius*, who were now evolving into monkeys and apes, diversified their diet somewhat, adding seeds and nuts to their diets along with occasional worms and insects (that may have been eaten more by accident than intent). Ultimately, however, that mostly vegan diet would prove not to be adaptive.

The First Meat Eating Primates

It was around 6 million years ago that the first *hominid* (or protohuman) entered the scene in Africa. *Sahelanthropus tchadensis* was a short, flat faced, small brained creature that represented a split from our closest relatives, the chimpanzees and apes. There is some convincing evidence that *Sahelanthropus*'s successors, such as *Australopithecus* did eat meat, at least occasionally. The meat which they obtained probably came through scavenging rather than through hunting (Blumenshine and Cavallo 1992). Eating raw meat, however, almost certainly comprised only a small percentage of the *australopith*'s diet since his gut (namely his stomach and intestines) was set up to process fruits and leaves. This means that he had a big cecum, which is a pouch at the beginning of the large intestine that contains lots of bacteria to help process fibrous materials. If an *australopith* gorged himself on a large quantity of raw meat, this could result in a twisting of the colon that would produce stomach pains and bloating and this might even result in death.

Successive versions of *hominids* had to deal with climate changes which affected the amount of rainfall that in turn affected the amount of grassy plants with seeds (like wheat and barley) and the availability of nuts. Both of these food sources are rich in fats but poor in fiber. Such a diet encourages the growth of the small intestine where the digestion of lipids occurs, and the shrinking of the cecum, where the digestion of fibers occurs. As the climate continued its steady change, much of the rain forest would have turned into sparsely wooded grasslands which, although providing fewer high-quality plants to eat, would be populated with more grazing animals which could now serve as a source of meat.

Later Hominids

By the time that *Homo erectus* appeared on the scene, significant changes had occurred in the gut which allowed meat to be eaten. Scavenging could still play a large part in the way in which meat was obtained. Recent research has shown that typically 95% of bones that are abandoned

by large predators still have some flesh remaining on them and over 50% have significant amounts of meat left (Pobiner 2015). It appears that early hominids often carried large bones and skulls back to their campsites. Using stone tools they could crack the skulls to get at the nutrient rich brains (which were very difficult for the hunting carnivores of the time to take advantage of). In addition, by using stone tools, they could crack the large bones to get at the fatty and calorie rich bone marrow inside.

The Expensive Organ Hypothesis

Homo erectus and his successors eventually began to actively hunt for meat. This new behavior required increased intelligence to outsmart the prey animals (after all fruits and vegetables don't try to run away) and to also support communication necessary for cooperative hunting. Hunting requires weapons, while stripping and processing flesh from the animals that are killed requires tools. Thus the major activities associated with hunting, and weapon and tool use, required a larger brain size.

The evolutionary problem is that brains are expensive. Modern human brains take up only around 2% of our body weight as adults yet they use about 20% of our energy. It is possible to offset some of the energy requirements for a large brain by reducing the size of the liver and gastrointestinal tract, since these, like the brain, are metabolically expensive tissues. But reducing the size of the gut is related to diet. Smaller guts require a diet that contains high-quality food that is easy to digest. The evolutionary solution was to take advantage of the nutritionally dense muscle mass of other animals. Some scientists have argued that without the abundance of calories afforded by meat eating, the human brain simply could not have evolved to its current form (Aiello and Wheeler 1995).

Culture and Cooking

Meanwhile, cultural and technological changes were also causing revolutions in our dietary

history. One of the principal events was the development of cooking. Cooked food is physically easier to chew and chemically easier to digest. This allows the extraction of more energy from the same amount of food. Cooking can also release more of certain nutrients than can be obtained from eating that same food raw. It can also render certain poisonous plants palatable. Cooking also saves energy that can be diverted to the brain (Wrangham 2009). One study looked at how Paleolithic food processing affected chewing force production and efficiency in humans consuming meat. It found that if meat comprised one-third of the diet, the number of chewing cycles per year would have declined by nearly 2 million (a 13% reduction) and also required 15% less bite force. Thus cooking combined with the availability of meat greatly increases the amount of energy available for that larger evolving brain (Zink and Lieberman 2016).

The Effects on Fertility

While increased meat eating was supporting the growth of the brain and intelligence, it appears that this change in diet also effectively increased human fertility. Recent research has shown that there is a strong connection between meat eating and the duration of breast-feeding. Data shows that all carnivorous species have relatively short periods of breast-feeding and early weaning compared to primate species whose diet is composed only of plant matter. This means that by shifting the diet of humans toward the consumption of more meat reduces the time between births. This increased fertility had an impact on human evolution and allowed the global spread of humans to accelerate (Psouni et al. 2012).

A History of Continuous Change

It appears that humans have bodies that are continually changing to cope with the availability of new foods. The case of organized

agriculture is the most clear. With agriculture, some human populations evolved extra copies of amylase genes, which allow them to be better able to deal with starchy foods. In response to animal husbandry and the keeping of animals that provide milk, several human populations independently evolved gene variants that coded for the production of lactase which breaks down lactose, a substance that comprises 2–8% of milk by weight. In some human groups, adults do not produce lactase and for them the eating or drinking of milk-based food results in lactose intolerance which has symptoms including abdominal pain, bloating, diarrhea, gas, and nausea.

Not all of these changes in the ability to utilize certain food sources are due to genetics. If we consider the digestive system of a typical mammal, we find a stomach that breaks down the protein, a small intestine that absorbs sugars and a large intestine that ferments and digests whatever plant material is left over. The length of the intestines is important. In humans, the large intestines are shorter than those of living apes relative to the overall size of our gut (more like 25% of the whole, compared to 46% of the whole in chimps). This shortness appears to make humans less able to obtain nutrients from the cellulose in plant material than are other primates. However, each stage of digestion requires the assistance of many gut bacteria. These make up the *microbiome* which has become an active area of study recently. The gut microbes can vary among different human populations, making some foods more or less digestible. Thus humans in Japan have a kind of bacteria in their guts which appears to have stolen genes for breaking down seaweed, a foodstuff that became popular along with rise of an agricultural Japanese diet. One current presumption is that our Stone Age ancestors, by eating a little bit more meat tended to cultivate more of the bacteria that help break down meat during digestion. These microbes were then passed on to successive generations during pregnancy and birth, thus giving their descendants a head start on the ability to process meat (Lambert 1998).

Drifting Away from Carnivory

One must not suggest that the natural course of evolution must inevitably be toward the eating of more meat. Remember, that we mentioned that during the agricultural revolution human beings began to pick up extra copies of the amylase gene, which allows them to process carbohydrates. An interesting case of a species evolving away from an intensively carnivorous, meat eating diet can be found in the comparison between wolves and dogs. Most of the genetic evidence says that the animals that we recognize as dogs emerged in the Neolithic period. That would be just about the time when humans were beginning to transition from a hunter-gatherer lifestyle to one involving agriculture and fixed settlements. Since dogs were domesticated around this time, it appears to have some implications for how dogs have diverged genetically from wolves and which resulted in dogs turning away from a purely meat-based diet.

To understand this, you must consider the scavenger hypothesis about how dogs were domesticated. This is the hypothesis which says that wild canines began to hang around human settlements to eat the scraps of food that humans tossed into their garbage heaps. Since this was the dawn of organized agriculture more grain-based starches and carbohydrates were beginning to make their way into the human diet. Through natural selection, the wild canines that could best process and survive on such a starch-based diet would obviously thrive the best and produce the most offspring. Over generations, natural selection would cause a set of genetic differences to evolve, eventually leading to our domesticated dog having an ability to process such foods more easily. In such a way, dogs would drift away from a purely carnivorous diet to one that could also utilize plant-based carbohydrates.

Recent research has shown that genetic differences have evolved between dogs and wolves. The strongest example is one alpha-amylase gene that is involved in the processing of starch in the pancreas. While the wolf genome carries 2 copies of this gene, dogs carry anywhere from 4 to 30 copies. Furthermore, chemicals associated with the digestion

of carbohydrates that are influenced by this gene are 28 times higher in the pancreas of dogs and nearly 5 times higher in their blood. Thus while the wolf remains a nearly obligatory carnivore, dogs can happily survive on a diet that is not solely based upon meat eating (Axelsson et al. 2013).

Conclusion

Thus the conclusion is that meat eating in humans and other species depends upon a number of factors. The availability of meat versus specific plant materials and the presence of a brain with high metabolic needs seem to be the forces most prominently driving the evolution of this behavior (Zaraska 2016).

Evolutionary Psychiatry

Bela Birkas
Medical School, Department of Behavioral
Sciences, University of Pecs, Pecs, Hungary

Synonyms

[Darwinian medicine](#); [Evolutionary mismatch](#);
[Vulnerability to mental disorders](#)

Definition

Evolutionary psychiatry applies the principles of evolutionary theory in psychiatric research and clinical practice. It utilizes and synthesizes similar theoretical models and research as Darwinian medicine, but focuses more on specific disciplines including psychology, psychiatry, and behavioral genetics. The evolutionary view of mental complaints highlights the role of functional capacities and biological adaptations in defining psychiatric disorders. This Darwinian approach provides an integrated biopsychosocial model for mental health and a theoretical framework for understanding human vulnerability to mental problems.

Introduction

Similar to Darwinian medicine, evolutionary models of psychiatric disorders contribute to a more comprehensive understanding of human

mental health and disorders (Brüne 2015). In order to describe the reasons why humans are vulnerable to mental problems, evolutionary psychiatry uses the same principles and explanations as Darwinian medicine (Nesse 2015). It emphasizes that selection processes formed human characteristics in order to serve our survival and/or reproduction and not to maintain our health. Evolutionary models of mental disorders also highlight the influence of the environments in which humans used to live and the effect of the rapid and excessive change of circumstances transforming *adaptive capacities* into risk for illness (Brüne 2015; Nesse 2015).

Functional Capacities and Mental Health

The criteria used to determine psychiatric disorders are based on the level, the extent, and temporal course of impairment (Troisi and McGuire 1998, 2002). However, to separate normal functioning from abnormal in terms of mental processes requires the evaluation of the appropriateness of a reaction or behavior to the situation (Nesse 2015). An integrated analysis of mental health including evolutionary models can help to separate normal and abnormal reactions or functions based on two key principles: (1) the *capacity to achieve biological goals* and (2) to *consider environmental factors* in which individuals live (Troisi and McGuire 1998, 2002).

Selection mechanisms favor psychological and behavioral traits that benefit the effective adaptation of the individual to certain environmental factors. Behavioral strategies enhancing individual evolutionary success include traits that enable the person to accomplish biological goals. A trait can be considered as adaptive if it can enhance the inclusive fitness of the individual. Nevertheless, different traits represent divergent forms of adaptations and they can be beneficial only in certain environments. Therefore, adaptations or functional traits are “case sensitive”; no trait is adaptive in every environment. Adaptations can enhance inclusive fitness in specific environments and if the circumstances change, they may no longer be functional or beneficial (Troisi and McGuire 1998, 2002).

Evolutionary psychiatry argues that the capability to achieve short-term biological goals is a valid indicator for adaptations, and functional capacities are predictive for future accomplishment of these goals. Correspondingly, focusing on functional capacities and biological benefits would allow clinicians to build up a more comprehensive assessment of the patients and the impairments linked to their disorders. Moreover, it contributes to the distinction of normal and abnormal behavior or characteristics and provides an integrated framework for psychiatric evaluation and diagnostics.

Individual Differences

Gene-environment interaction plays an important role in explaining individual vulnerability, that is, why some individuals get ill while others in the same environment do not. Correspondingly, the interplay between genes and environmental factors is acknowledged as a dominant causal factor creating individual differences in proneness to develop mental disorders. However, to understand and explain how genotype interacts with environmental factors is highly difficult. Moreover, other factors can also affect variations among individuals: differences can be caused by differences in genes, environmental factors, or by the interactions of these two key factors (Brüne 2015).

As pointed out earlier, models of evolutionary psychiatry share the vast majority of explanation and principles of Darwinian medicine. Accordingly, individual vulnerability to psychiatric disorders can be influenced by mechanisms, which can be also accounted for influence individual risk of physiological or somatic illness. Effects of trauma, toxins, or other harmful conditions, or cultural and interpersonal experiences guiding the development of social competences can also increase or decrease the vulnerability of the individual. Several random factors (e.g., neural development) or contrariwise, nonrandom factors, such as *assortative mating* (homogamy), finding a partner with highly similar characteristics and probably with similar genotype can also impact the development of individual differences (Nesse 2015).

Conclusion

Evolutionary psychiatry is based on two key points: First, Darwinian models of mental health are outcome-centered, thus, conditions considered as pathological have harmful consequences for the individual. Consequences of the environmental factors, which can be detrimental in case of insufficient adaptation, are primarily emphasized as casual factors and not the circumstances per se. Second, environmental factors determine the efficiency of functional capacities. Optimal conditions can moderate or even overrule inadequate functions, whereas more disadvantageous environments might compromise the adaptability of these capacities. Consequently, functional impairment and biological adaptation are the fundaments of evolutionary psychiatry.

Evolutionary Psychology and Intimate Partner Violence

Evita March
Federation University Australia,
Berwick, VIC, Australia

Synonyms

[Domestic violence](#); [Infidelity](#); [Partner-directed violence](#); [Sexual conflict theory](#); [Sexual jealousy](#)

Definition

Intimate partner violence (IPV) refers to when an individual attempts to harm or control their

current/former romantic partner, in a manner that is against that partner's will (Chester and DeWall 2018). Broadly, IPV includes physical, psychological/emotional, and/or sexual forms of abuse (Arnocky et al. 2015; Caldwell et al. 2012). Intimate partner stalking has also been conceptualized as a form of IPV (Norris et al. 2011).

Introduction

Worldwide, IPV prevalence estimates are high, with World Health Organization statistics indicating that almost one third of women almost one third of women report having experienced some form of physical and/or sexual violence by their intimate partner in their lifetime (World Health Organisation 2017). Although women, particularly younger women, are more likely to experience IPV (Sugg 2015), it should be noted that women also perpetrate violence toward partners, and as such a comprehensive overview of IPV should also include consideration of women-initiated violence (see Buss and Duntley 2011). Both men and women engage in vigilant and violent behaviors in an attempt to protect and defend mating relationships (Buss and Shackelford 1997).

A range of theoretical perspectives have been applied in an attempt to understand and examine IPV, including considerations of cultural and societal conditions (e.g., Brownmiller 1975) and psychological perspectives, such as evolutionary psychology. These approaches are not considered mutually exclusive; Chester and DeWall (2018) highlight that IPV likely results from a combination of multiple processes.

In this entry, evolutionary psychology perspectives of IPV are presented and discussed. Specifically, this entry will consider the evolved mechanisms that are considered to motivate and perpetuate IPV. The following sections will be discussed: (1) sexual conflict theory, (2) jealousy and sexual control, and (3) other adaptive problems and IPV. Finally, additional considerations and a conclusion will be provided.

Sexual Conflict Theory

To begin understanding the occurrence of IPV, Buss and Duntley (2011) recommend consideration of sexual conflict theory, a broad framework for understanding sexual conflict that occurs between males and females. Sexual conflict occurs when there are contrasting reproductive strategies for the sexes (Bonduriansky et al. 2008); specifically, the reproductive success for one sex potentially harms the reproductive potential for the other sex (see Promislow 2003). For example, the tendency for females to be the "choosier" sex (a strategy to promote their own potential reproductive success) potentially conflicts with the male tendency to acquire many sexual mates (a strategy to promote their own potential reproductive success). Such sexual conflict can occur across all stages of the relationship: before mating has taken place, during the relationship, and relationship termination/aftermath (Buss and Duntley 2011). In sum sexual conflict theory provides an appreciation for understanding that conflict in mating relationships is expected and common (Buss and Duntley 2011). However, although such theory provides a framework for understanding why conflict may occur, this does not condone or excuse violent and aggressive behavioral tactics employed in relationships (Buss and Duntley 2011).

Jealousy and Sexual Control

According to evolutionary perspectives, IPV may have evolved as it facilitated survival and reproductive goals; further, reproductive benefits gained from IPV ensured continued perpetuation of this behavior (Chester and DeWall 2018). In this section, I discuss reproductive benefits that may be facilitated by IPV.

Such violent behaviors enacted by men and women may be fuelled by jealousy (Shackelford and Duntley 2008). Jealousy, an emotion experienced when a relationship is threatened by a real or imaginary rival, primarily functions as a mechanism to maintain relationships (Goetz 2010). Although both men and women

experience jealousy as a reaction to threatened relationships, a sex difference is often seen in the type of jealousy experienced (Goetz 2010). Specifically, women are more likely to experience emotional jealousy and men are more likely to experience sexual jealousy; this sex difference is directly attributable to adaptive costs associated with the sexes (Goetz et al. 2008b). Men's emotional infidelity could threaten women's reproductive potential to secure a mate who will provide the necessary resources to ensure offspring survival, whereas women's sexual infidelity could threaten men's reproductive potential of paternity certainty, thus resulting in cuckoldry (Goetz 2010). Research has also shown men and women to be particularly jealous of rivals that might increase a mate's reproductive potential; for example, women are more upset by a physically attractive rival, whereas men are more upset by a rival with high status and resources (Brase et al. 2004).

This sex difference in jealousy has been replicated in a range of studies, ranging from self-report (Sagarin et al. 2003), experimental studies (Thomson et al. 2007), and physiological evidence (Buss et al. 1992). Regarding IPV, men's sexual jealousy is one of the most frequently cited causes (Buss as cited in Goetz et al. 2008b). The reproductive costs of mate infidelity and cuckoldry are considered so great for men that they have evolved to be particularly sensitive to sexual infidelity (Kaighobadi et al. 2009a); and IPV is a behavioral output of this sexual jealousy. Jealousy is viewed as an extremely important factor in men's violence against women (Puente and Cohen 2003).

Due to internal female fertilization processes and ovulation, men's genetic relatedness and paternity of offspring can remain relatively uncertain (Arnocky et al. 2015). As such, a man's ability to anticipate and prevent mate sexual infidelity has particular strong reproductive benefits (Starratt et al. 2007). Men may have evolved psychological mechanisms that motivate behaviors designed to prevent their partners from performing costly reproductive behaviors, such as being sexually unfaithful or terminating the relationship (Miner et al. 2009b; Starratt

and Shackelford 2012). According to initial researchers in this field, to prevent and overcome paternity uncertainty, males exert control over females' sexuality – referred to as “male sexual proprietariness” (Wilson and Daly 1996). As such, IPV is a tactic used to restrict and ultimately control a female mate's sexual behavior (Daly et al. 1982; Wilson and Daly 1993). IPV is not about controlling females, but controlling their sexuality (Wilson and Daly 1993).

If male-perpetrated IPV is an evolved mechanism to control females' sexuality and deter infidelity and relationship termination, then according to this hypothesis, IPV should vary with women's reproductive potential – assessable by age (see Wilson and Daly 1993). In 2002, Peters, Shackelford, and Buss tested the hypothesis that IPV rates would vary with women's reproductive value; specifically, IPV would decrease as female age increased. Data was collected from the United States-based police incident reports concerning nonlethal domestic disturbance; these reports are provided to the Domestic Violence Prevention Project (DVPP) of Safe Horizon, whom then provided the researchers with the data. In total, there were 3,969 cases involving 1 female victim and 1 male perpetrator. The average age of victims was 32.7 years ($SD = 9.3$), and the average age of perpetrators was 35.1 years ($SD = 9.6$). Data showed women in the youngest age category (aged 15–24 years) were at greatest risk of experiencing IPV (twice as high as the next age category [aged 25–34 years]), and these rates declined with age. Further, data also showed that although IPV was most often perpetrated by younger men, women were most likely to experience IPV when mated to a man two age categories older. As such, the authors concluded that the risk women experiencing IPV cannot be attributed to mating with younger, violent men. Peters et al. (2002) concluded that the findings based on the data were consistent with the hypothesis that IPV functions to control women's sexual behavior during her reproductive years. This pattern of results has also been demonstrated outside of research testing evolutionary hypotheses (age-IPV curve; Johnson et al. 2015).

A significant amount of research has supported the relationship between infidelity suspicion and prevention and IPV (Wilson and Daly 1998, provide a review). Different forms of violence may be enacted for different purposes; for example, physical aggression might punish a partner for infidelity or discourage the partner from future indiscretions (Arnocky et al. 2015), whereas psychological aggression might serve to reduce a mate's self-esteem, thus exercising further control (Buss 1994/2003/2016). Further substantiating the importance of the importance of infidelity suspicion when enacting IPV, research has shown the relationship between personality traits (e.g., emotional stability, agreeableness, and conscientiousness) and partner-directed violence to be dependent on risk perceptions of partner infidelity (Kaighobadi et al. 2009b).

It is important to note that suspicion of partner infidelity may not initially escalate to violence, and a temporal hierarchy may exist between nonviolent and violent mate retention behaviors. Kaighobadi et al. (2008) tested the hypothesis that accusations of female infidelity would predict men's partner-directed violence across two studies (men's self-reports and women's partner reports). Results indicated that female sexual infidelity was positively related to IPV; further, nonviolent mate-guarding behaviors mediated the relationship between accusations of infidelity and female-directed IPV. To explain this mediation, the authors speculated a temporal hierarchy between nonviolent and violent mate retention behaviors. Specifically, men may initially enact less costly nonviolent behaviors before ending in acts of violence.

A final consideration here regards the interesting relationship humans have with jealousy. Specifically, humans tend to interpret acts of jealousy as acts of love, an interesting trend given the relationship between sexual jealousy, infidelity suspicion, and IPV. Over three studies, Puente and Cohen (2003) explored observer interpretations of acts as jealousy. Participants were presented with a jealous man who abused his wife and a jealous man who did not abuse his wife. Results indicated that participants believed jealousy to be a sign of love and did not believe

jealousy-related violence indicated a lack of love. Participants viewed the jealous man who abused his wife and the jealous husband who did not abuse his wife as similarly loving. Importantly (and concerning), participants viewed the abusive, jealous man as significantly more loving than the nonviolent, non-jealous man.

Sexual coercion and IPV. A particular type of IPV – sexual coercion – is also hypothesized to manifest from suspicions of sexual infidelity (Goetz et al. 2008a) and male sexual jealousy (Kaighobadi et al. 2009b). Sexual coercion refers to “the use of force, intimidation, lying, or psychoactive substances to receive or perform sexual acts” (Gladden et al. 2008, p. 319). Here, I refer to sexual coercion within relationships. Physical abuse in a relationship has been shown to be a reliable predictor of sexual coercion (Shackelford and Goetz 2004), and men's suspicion of partner infidelity has also been linked to increased sexual coercion (Goetz and Shackelford 2009). Sexual coercion in relationships has been attributed to men's motivation to achieve dominance over and control his partner (see Goetz and Shackelford 2009, for a full discussion) and evolutionary perspectives. Specifically, sexual coercion may have evolved in response to infidelity and cuckoldry and may function to introduce the male's sperm into the female to be in direct competition with any rival male's sperm (Goetz et al. 2008b; Starratt and Shackelford 2008). Given the high reproductive costs of female infidelity and cuckoldry, sexual coercion, and in turn sexual violence, in relationships may have evolved as an “anti-cuckoldry” strategy (Starratt and Shackelford 2008).

In sum, research has shown sexual coercion to be predicted by both partner infidelity suspicions and male control (Goetz and Shackelford 2009); as such, both of these predictors provide adequate interpretation for perpetrating sexual IPV.

Other Adaptive Problems and IPV

Mate value. Although the evolved violent behavior enacted to avoid sexual infidelity and relationship termination is often cited as a key

explanatory perspective of IPV, there are other adaptive problems men and women might face in which IPV could be employed. One of these adaptive problems concerns an imbalance in mate value.

Assortative mating refers to a nonrandom mating pattern where mates express more similar phenotypes than would be expected by random mating (Buss and Duntley 2011). Mate value, one of the strongest domains of assortative mating, is defined as the genetic quality of oneself as a sexual partner, displayed through observable characteristics (Kirsner et al. 2003). Despite this initial definition, Fisher et al. (2008) argue that mate value need not exclusively depend on reproductive characteristics and suggest mate value is defined as “the total sum of characteristics an individual possesses at a given moment and within a particular context that impacts on their ability to successfully find, attract, and retain a mate” (p. 157).

An imbalance in mate value arises when the value of one mate may exceed, or be considered inadequate, to the value of the other mate. For example, status and resources are considered, cross-culturally, to be important determinants of a man’s mate value, whereas physical attractiveness is considered, cross-culturally, to be important determinants of a woman’s mate value (Buss et al. 1990). A mate value imbalance could exist when one mate possesses a high level of the characteristics desired by the opposite sex. Alternatively, a man might consider himself to be at a competitive disadvantage with other competitors if he has less of the characteristics (i.e., status and resources) desired by the opposite sex (thus lower mate value; Figueredo et al. 2012).

Buss and Duntley (2011) discussed how mate value discrepancies can trigger a causal chain of behavior, leading to IPV. Specifically, higher mate value (particularly of women) increases the likeliness of infidelity. Higher mate value also increases the likeliness of relationship termination. Finally, men’s lower mate value is usually associated with lower status and resources, characteristics women desire in a mate. Due to this lower mate value and inability to provide desired resources, this increases the likelihood of

a woman committing infidelity or terminating the relationship. This causal chain therefore increases the likelihood of IPV, particularly male-directed violence.

Although somewhat limited, there is evidence that mate value discrepancy in a relationship predicts IPV behaviors; the mate lower in mate value is more likely to express controlling and aggressive behavior toward their mate. An imbalance in mate value in a relationship has even been shown to predict nonviolent relationship behavior. In a sample of 158 women, Miner et al. (2009a) asked participants to provide information about their own mate value, their partner’s mate value, and their partner’s verbal insults. Male mate value, compared to female mate value, was found to be a better predictor of men’s verbal insults directed at the partner. Further, when the man had lower mate value than the woman, the verbal insults were more frequent. It should be noted though that low mate value may be inexplicitly linked to sexual jealousy (Figueredo et al. 2012). As such, low mate value may therefore be a better explanation for experiencing sexual jealousy, which in turn predicts perpetration of IPV.

Sex ratio. An evolutionary psychology perspective also posits that a high sex ratio (i.e., more of one sex than another) will induce intersex competition. For example, when there are more men than women in the population, this increases competition between men for access to women. Specifically, as the proportion of men to women in a population increases, men may become increasingly concerned about infidelity; this in turn fuels sexual jealousy which, as discussed above, perpetuates IPV (see Wilson and Daly 1998). This produces a rather simple hypothesis; in a population where there are more men than women, there should be an increase IPV. Not all research has shown this relationship, with South and Messner (1987) finding no relationship between sex ratio and homicide data drawn from Supplemental Homicide Reports. However, given the relative infrequency of intimate partner homicide, such indices may not be a reliable assessment of the occurrence of IPV; indeed, South and Messner (1987) indicated that future research

should explore the relationship between sex ratio and female victimization in non-homicidal violence. To explore this relationship, D'Alessio and Stolzenberg (2010) assessed data from the Federal Bureau of Investigation's National Incident-Based Reporting System (NIBRS) and the US Census for reports of male-on-female intimate partner violence. Results showed that after controlling for a variety of factors (e.g., income, race), a high sex ratio is a significant predictor of increased male-on-female IPV. D'Alessio and Stolzenberg (2010) posit that their data supports an evolutionary perspective; the disparate sex ratio increases intersex competition, and as such men use IPV as a mechanism to control their mate's sexual behavior. The link between sex ratio and IPV has been replicated in other research; for example, La Mattina (2013) found that in post-genocide Rwanda where there was a significant decrease in the number of men (thus significant disparate sex ratio between men and women), there was a significant increase in occurrence of IPV.

Resource infidelity and scarcity. Buss and Duntley (2011) discuss resource infidelity and scarcity are two circumstances that could possibly eventuate in mate-directed violence. Resource infidelity is described as diverting resources away from the mate and offspring and directing these resources toward extra-pair mating (Buss and Duntley 2011). Such resource infidelity can occur for men and women; however, given the importance women place on status and resources in a relationship (see Buss et al. 1990), resource infidelity might provoke a stronger jealous response in women. Although research has not yet specifically explored resource infidelity as a precursor to IPV, Buss and Duntley (2011) suggest that this is a predictable form of couple conflict which could result in aggression and violence.

Like resource infidelity, resource scarcity might also be perpetuate conflict in a relationship, which could result in IPV. Resource scarcity refers to the insufficient supply of provision of resources in the relationship. This resource deficit might have been present from the onset of the relationship, such that the mate is of lower

mate value in comparison to competitors. Alternatively, the resource scarcity might have eventuated during the course of the relationship, owing to financial hardship, job termination, etc. In either circumstance, these men experiencing resource scarcity might use cost-inflicting tactics as a way to maintain the relationship, preventing infidelity and relationship desertion (Wilson and Daly 1993). Research supports this premise, with links documented between economic hardship and increased IPV (see Flynn and Graham 2010). In sum, the failure for men to provide the resources women necessitate in mateship could trigger couple conflict, which in turn could perpetuate IPV.

Relationship termination. IPV may also function to prevent the mate from leaving the relationship or to encourage relationship reacquisition. Further, IPV may also act as an encouragement for the mate to reenter the relationship after termination. After one mate has defected from the relationship, the other might employ violent strategies in an attempt to convince the mate to return (e.g., stalking). Wilson and Daly (1998) suggest that mate-directed violence could be employed as a "final" effort to salvage a relationship, threatening the mate that intends to leave. Although this might not always work (and may even hasten the relationship termination), in some cases this act of violence might deter the mate from leaving, thus reinforcing the use of violence in the future. As Perilloux and Buss (2008) discuss, if a man can force a woman to remain in a relationship, then he has overcome her ability to choose a mate, one of the most crucial components of a female mating strategy.

Other contributing factors. Primarily, an evolutionary psychology perspective of IPV focuses on controlling a mate's sexuality and deterring infidelity or possible relationship termination. However, there are other notable factors that may contribute to perpetuating IPV, such as the quality of sex in the relationship, economic resources (Figueredo and McCloskey 1993), and a lack of female kin protection (Smuts 1992). Other contributing factors include childhood socialization and control of anger

(Wilson and Daly 1993) and anxiety (Arnocky et al. 2015).

Recently, researchers found anxiety to have a particularly important role in the perpetration of IPV. In a sample of 66 participants, Arnocky et al. (2015) found that anxiety mediated relationships between anticipated partner infidelity and aggression (physical, psychological, and sexual). Anxiety is an emotion that has evolved as an adaptive response to threats; as such, it is reasonable to expect that the relationship between the possible threat and behavior (i.e., infidelity and violence) is dependent on responding to the threat (i.e., anxiety).

Finally, a consideration of neurobiology (see Wilson and Daly 1993) provides interesting future directions for evolutionary psychology perspectives of IPV. In a double-blind, placebo-controlled, between-subjects experiment, DeWall et al. (2014) found that oxytocin (a nonapeptide) increased IPV inclinations, as assessed by the probability participants would engage in various partner-directed aggressive behaviors (e.g., slapping, throwing an object that could hurt). However, this effect was limited to individuals with higher levels of trait physical aggression. These results provide the first evidence of a biological basis of IPV and provide a possible framework for future researchers examining IPV through an evolutionary psychology lens.

Conclusion

Exploring IPV through the lens of evolutionary psychology attributes the behavior to evolved mechanisms designed to overcome reproductive threats and limitations. Understanding the etiology of IPV provides a framework for intervention and prevention of the occurrence of violence in a relationship (Peters et al. 2002). This entry has provided an evolutionary perspective to explain and understand IPV; however, it should be noted that while this perspective provides an adequate explanation, there are many other factors and perspectives that have not been discussed. Despite this, an evolutionary psychology perspective

can guide research on exploring the mechanisms that have evolved to motivate IPV (Kaighobadi et al. 2009a).

Evolutionary Psychology, The Handbook of

David M. Buss
Department of Psychology, University of Texas at Austin, Austin, TX, USA

Synonyms

Evolutionary psychology; Handbook

Definition

A compilation of 52 chapters and essays, written by evolutionary scientists, summarizing theories and research in major branches of evolutionary psychology.

Introduction

Charles Darwin was the first evolutionary psychologist. He described his vision for the future of psychology at the end of his classic 1859 treatise *On the Origin*: “In the distant future I see open fields for more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation.” Close to a century and a half later, his prophecy began to come to fruition. *The Handbook of Evolutionary Psychology*, first published in 2005, logged in at more than 1,000 printed pages with some 35 chapters (Buss 2005). The second *Handbook of Evolutionary Psychology*, published in 2016 with more than 52 chapters and essays, highlights how dramatically the field has expanded. Darwin turned out to be right (Buss 2016).

What the Handbook Showcases

The *Handbook* showcases “the best and the brightest” in the field, although space limitations required excluding many major players. It reveals several important developments in the actualization of Darwin’s vision. First, evolutionary psychology serves as a “metatheory” for the entire field of psychology (Buss 1995; Tooby and Cosmides 1992). It is not a subbranch of psychology, but rather a metatheoretical framework within which all psychology becomes organized and integrated. Stated differently, there is no such “non-evolutionary psychology” in the sense that no other causal processes, other than evolutionary ones, are responsible for whatever psychological machinery humans possess. The evolutionary metatheory currently organizes biology and all of the life sciences, and there is no reason why psychology should be magically exempt.

Second, evolutionary psychology has penetrated every single branch of the traditionally delineated branches of psychology – sensation, perception, cognitive, social, personality, developmental, clinical, and neuroscience. Individual chapters on these topics showcase the utility of evolutionary perspectives in discovering phenomena previously missed by approaches lacking an evolutionary lens. Examples include the vertical descent illusion in vision,

cross-sex mind-reading biases in social cognition, the predictable developmental emergence of phenomena such as stranger anxiety, important psychological sex differences where previous psychologists assumed monomorphism, and many others.

Third, the *Handbook* showcases the many emerging interdisciplinary enterprises, such as evolutionary endocrinology, evolutionary political science, evolutionary genetics, and cultural evolution. A strong case can be made syllogistically: All human behavior rests on a foundation of evolved psychological mechanisms; all such complex mechanisms owe their existence to evolution by selection; therefore, all fields that involve human behavior must have evolutionary psychology as a foundational explanatory framework. The expansion of evolutionary psychology into disciplines such as political science, sociology, economics, and even literature and the formation of new hybrid disciplines with evolutionary theory as their organizing core are hallmarks of the future and herald a consilience of the sort envisioned by E. O. Wilson (1999).

Fourth, the *Handbook* highlights that massive and rapidly expanding empirical foundation of the new science of the mind. Early in its inception, evolutionary psychology was viewed as a highly speculative enterprise. Some derided it as “just-so stories,” with the implication that it more resembled cocktail party musings rather than serious, testable, and falsifiable empirical science. The *Handbook* shows that, although evolutionary psychological hypotheses do span the spectrum of precise and testable to looser and less amenable to empirical rigor, there is no doubt that evolutionary psychology consists largely of sound empirical science. Every year, the empirical edifice grows. New discoveries are made using the theoretical lenses of the field. And knowledge about the science of the mind accumulates within EP’s cogent metatheoretical framework, each new discovery building on the others in a way that makes the growth of scientific knowledge truly satisfying.

Another development showcased by the *Handbook* is the fact that competing evolutionary psychological hypotheses are increasingly being advanced and pitted against each other in empirical test. Outsiders sometimes ask what “the” evolutionary hypothesis is about a particular phenomenon. As shown in cases such as the

female orgasm, menstrual cycle shifts in women's mate preferences, and adaptationists versus by-product hypotheses about homicide, competing evolutionary hypotheses act as fulcrums, catapulting the field forward.

Finally, the *Handbook* reveals that evolutionary psychology has become a sufficiently mature science to generate practical applications or to become "translational" in the current jargon of the field. The *Handbook* provides a sampling of these – evolutionary consumer behavior, organizational leadership, and the law. These developments auger well for future translational applications of the new science of the mind.

Conclusion

The *Handbook of Evolutionary Psychology* should be a core reference manual on the shelf or computer of every scientist who deals with human behavior. Evolutionary psychology is no longer an optional exercise. It guides researchers to important domains of inquiry. It reveals facets of human psychology previously undiscovered. It provides a metatheory that provides a justification for why all the different branches of psychology belong within the covers of the same book. And it provides the foundation from which all disciplines that deal with human behavior can be enlightened. Darwin prophesied that psychology would someday be based on a new foundation. That day has come. The foundation is now firmly in place. Future researchers can now use that foundation to construct the larger edifice – the mature science of the human mind that Darwin envisioned.

Definition

Evolutionary social psychology is the study of the adaptive psychological mechanisms through

which real or imagined others affect individuals' cognition, emotions, and behaviors. This definition is a slight modification of one classically used to define social psychology that reflects the modular approach to human behavior typical of evolutionary psychology.

Introduction

Social psychology is arguably the second oldest of the modern fields of psychology. The first social psychology textbook (McDougall 1908) was published not long after the first psychology textbook was published (James 1890). Even in those earliest days of social psychology, the field had an appreciation of the role of evolution in human social behavior. The typical approach to social behavior, whose origin is often attributed to Kurt Lewin, emphasizes the interaction between trait-like individual differences and dynamic situational factors. This approach is not unlike that approach adopted in evolutionary psychology. Evolutionary psychology assumes that evolution has shaped the mind into a modular network of psychological mechanisms, each designed to address specific recurrent adaptive problems (Tooby and Cosmides 2005). Researchers assume that mechanisms are sensitive to various inputs from the environment, which then elicit a subset of reactions (cognitive, affective, and behavioral) that address the problem people face. This is roughly analogous to the person by situation interaction approach assumed in traditional psychology. Perhaps it is for these reasons that social psychology was among the first to reincorporate an evolutionary framework.

Examining human social behavior from the perspective of evolutionary biology has been very fruitful. Almost every major area of social psychology has benefited from utilizing an adaptationist approach (Tybur et al. 2009). Approaching human social behavior from the perspective of evolutionary biology, by identifying the adaptive problems faced by in human social life and attempting to identify the adaptive modules shaped by selection (natural and sexual) to resolve those problems, has provided direction previously unavailable. It has

done so, not only by suggesting novel research questions but also by providing a potential organizing framework to a field that, traditionally, has been highly splintered.

In the following review, we will explore some of the advances that the evolutionary approach has provided. First, we will review ideas that have been employed repeatedly in our understanding of human social behavior. We will then turn to how these ideas have shaped our understanding of how people think about others. It should be noted that this review is not meant to be exhaustive, and the reader is encouraged to explore the wealth of ideas and research that has been generated by this evolutionary approach to social psychology. First, we will review some recurring concepts.

Recurrent Concepts

Social psychology has benefited from many ideas that follow from evolutionary biology. While, we would direct the reader to the relevant entries within this volume for more in-depth coverage of these concepts, we address some of the major factors that have proven useful in delineating the psychological mechanisms that have emerged due to the selective pressures of social living. These concepts include the costs of false positives and false negatives and sexual selection. First, we will briefly revisit the concept of a psychological mechanism.

Psychological Mechanisms. A psychological mechanism is any module of the mind, which processes specific, adaptively relevant information, and generates output in the form of thoughts, emotions, or behavioral inclinations (Tooby and Cosmides 2005). A psychological mechanism is a module shaped by selection pressures in the same way that the eye is a sensory module, or the heart is a cardiovascular module. They develop as a solution to an adaptive problem persistently faced across evolutionary history. The eye is an old biological module originally thought to have developed for the regulation of the circadian rhythm and other biological processes and later modified to facilitate navigation. The heart is a still older biological module designed to address

the adaptive problem of pushing vital fluids, proteins, and nutrients throughout an organism's body. In the same way, psychological mechanisms arise as the result of neurobiological modules designed to address recurrent and persistent adaptive problems created by human social life, some of which, like the eye, may have been modified to facilitate new functions.

It takes time for environmental contingencies to shape genotypes. For example, if a genotype produces a phenotype that successfully helps its possessor overcome an environmental or social challenge with greater frequency than are other members of the same species able to, then that individual *may* reproduce more successfully. However, even if this individual has many offspring, and each of those offspring have many offspring of their own, and on and on, it takes many generations for that genotype to become common for the entire species; and this process is slowed by the extent to which offspring do not share the advantageous quality.

It is for this reason that many modern advances and changes cannot have had an enduring change on the psychological mechanisms that comprise current human social nature. Social media, the Internet, or even modern cultural advances and the new selection pressures they may introduce have not had the time to shape the typical genotype of the species. For this reason, evolutionary social psychology emphasizes the selection pressures created by social life that have endured across many thousands of years, well into our approximate 200,000-year history as a species and beyond.

Living in groups creates numerous and diverse selection pressures. These challenges include problems such as avoiding pathogens that one might encounter when interacting with others (Schaller 2006), correctly identifying the intentions of other social agents (e.g., do they want to harm me, do they want to mate with me), identifying the best possible mates, and successfully navigating group life. We will now turn to some of the common evolutionary processes and factors involved in solving these selection pressures. We will then explore what these factors' application has revealed about human behavior.

False Positives and False Negatives

We get a lot of information from our environment. Some of this information is useful, in that it can help us make decisions that help others or us. However, not all of this information is useful. Some of this information is entirely irrelevant to the decisions we make. In signal detection terms, useful information can be thought of as a signal, while useless information can be thought of as noise. Signals are usually embedded among noise. Take for instance when trying to write an encyclopedia entry in your office and hearing what you think might have been the buzz of your silenced phone indicating that you have received a message. The signal in this scenario is the buzz from the silenced phone. Colleagues talking in the hallway, electronic devices of various types humming, and wind from outside the office window all create signal irrelevant noise. We signal detectors must determine whether signals (the message notification on our phones) are present among the noise.

If we correctly identify a signal when it is present, then in terms of signal detection, we have a hit. If we correctly identify that a signal is absent, then we have a correct rejection. However, sometimes the noise can so obscure the signal that our ability to detect the signal can falter. If we incorrectly identify a signal as being present when it is not, then we have a false positive. If we incorrectly identify a signal as being absent when it is present, then we have a false negative or a miss.

All animals must detect useful signals that indicate the presence of adaptive problems in their environments, and, as social animals, we humans must detect signals in our social environments. Sometimes, incorrectly identifying the presence of a cue is non-consequential. However, this is not always the case. When false positives and false negatives are consequential and these consequences persist across time, evolutionary logic holds that we will develop signal detection biases that result in the least harmful consequence (Haselton and Buss 2000). That is, if it is safer or more advantageous to guess that a signal is present when it is not, then we will adopt a liberal

response bias and err toward guessing that signals are present when we are less than certain. On the other hand, if it is safer or more advantageous to guess that a signal is absent when it is present, then we will adopt a conservative response bias and err toward guessing that signals are absent when we are less than certain.

Sexual Selection

As pervasive a process as natural selection is, adaptations also develop within sexual species by way of sexual selection. Because sexual species, like humans, reproduce with other members of the same species and produce offspring with genotypes that reflect a combination of both parents, the needs of each sex create selection pressures for the opposite sex (Buss and Schmitt 1993). That is, those who meet the needs of the opposite sex have greater chances of reproducing successfully than do those who do not meet those needs. As males and females have shared the lion's share of adaptive problems, males and females are largely more similar than they are dissimilar. However, in the context of reproduction and bearing offspring, the adaptive problems faced by each sex have diverged.

Prior to the advent of modern methods of determining paternity, males had no way of being certain of their paternity. This created selection pressures on males that females did not experience, given that females were always completely certain of their paternity. On the other hand, females have faced a different adaptive problem. Specifically, females are more invested in the bearing of offspring. This is the case even if they relinquish responsibility for rearing their offspring. Human offspring gestate in females for approximately 32 weeks. During that time, mothers are responsible for providing for their gestating offspring's every need. As many mothers might attest, this responsibility can be temporally, calorically, and mentally demanding. Further, males can share these tasks only to a very limited extent. Beyond birth, provided mothers choose to continue tending to their children,

females are one of principle providers for their infant's nutritional needs (i.e., breastfeeding). This is also something that males can share to a very limited extent. Beyond these differences, which are largely a product of the physical machinery involved in gestation and lactation, males and females' investments in offspring can largely, if not entirely, converge. However, these differences create powerful selection pressures for human females in the vast majority of mammalian species.

Trivers (1972) proposed that this adaptive problem of parental investment has led to sex differences in certain aspects of mating behaviors. Specifically, as females are more invested in bearing and rearing offspring, copulating with all males is not equally beneficial. In fact, copulating with some males might be harmful as they may impose certain genotypic burdens, health burdens, and social burdens. Therefore, Trivers argued that females would be more discriminating in their mate choices, while males, on the other hand, would be more likely to compete with one another for access to mates more heavily than would females. Indeed, this increased competition is thought to be one of the reasons for the sex differences in size across species. Typically, the least invested sex, and therefore, the sex that competes the most for mates, is larger than their more invested, less competitive counterparts. We see this sexual dimorphism in those species in which females are more invested in the bearing and rearing of offspring, including humans. Indeed, some anecdotal examples from history suggest that this increased competition may be at least partially responsible for some of the warmongering in our species history (Daly and Wilson 1988). Take, for instance, the following quote attributed to Genghis Khan.

The greatest happiness is to vanquish your enemies, to chase them before you, to rob them of their wealth, to see those dear to them bathed in tears, to clasp to your bosom their wives and daughters.

Interestingly, when this investment asymmetry is reversed, we see a reversal of these general patterns of sexual dimorphism. That is, in species in which males invest more in the bearing and

rearing of offspring, the females compete more heavily and are often physically larger. Examples of this reversal can be found in phalarope birds, Mormon crickets, and seahorses.

Shaping Human Social Nature

We will now turn our attention to how these forces (and others) have advanced the study of social psychology. Evolutionary researchers have fruitfully applied the principles of evolutionary biology to many, if not most, of the fields in social psychology. It is far beyond the scope of this entry to review this work in its entirety. However, we will discuss how evolutionary reasoning has advanced the study of person perception.

Person Perception

Person perception is a subarea of social psychology in which researchers focus on the processes involved in the detection, categorization, and interpretation of others' behaviors. Person perception researchers often explore how we make inferences about others' intentions (e.g., is this person a friend, foe, or romantic flame). Work in evolutionary psychology has illuminated how certain selection pressures have shaped the inferences people form of others' intentions.

Two fundamental dimensions on which people tend to form impressions include the extent to which others want to harm or help us (i.e., warmth) and the extent to which they are capable of doing what they set out to do (i.e., competence, Cuddy et al. 2008). People often want to know whether someone wants to hurt them before caring whether they can. Therefore, here we will explore what an adaptationist approach to the study of impression formation reveals about the impressions we form of others' warmth.

First Impressions

Research examining first impressions reveals that people make judgments about others' internal qualities in as little as a tenth of a second (Willis

and Todorov 2006). Because we make these judgments so quickly, they utilize a very thin slice of information (Ambady and Rosenthal 1993) about other people in order to make these judgments. That is, people often form judgments of others based on superficial, observable features. Interestingly, research examining the first impressions that people form based on these superficial features have revealed that we extract information relevant to some of the adaptive problems that social living has presented us with and form our impressions based on this information.

When meeting new people, we must determine whether we should interact or not. Therefore, interacting with strangers creates a selection pressure. Interacting with any new person could create a survival relevant contingency for a number of reasons. One reason is that other people may want to hurt us. A second reason is that those new people may carry diseases, which might infect us, harming us unintentionally. Work has revealed that our first impressions glean information relevant to these concerns.

Mechanisms for Avoiding Harm in Person Perception

Our assumptions concerning whether strangers want to hurt us depend on our quickly made impressions of others' interpersonal warmth. Several pieces of information available at first glance inform these impressions concerning others' warmth. These include the presence of baby-faced features, similarity, sex, and outgroup membership.

Humans have a prolonged developmental period. As infants, we, therefore, require the aid of older individuals to survive. Researchers have proposed a suite of psychological mechanisms that might address this adaptive problem. One of which, thought to facilitate caring for infants appears to influence the impressions we form of others' warmth. Specifically, this mechanism responds to cues of infancy with a cute response. The cute response involves reactions of protectiveness and careful behavior (Sherman et al. 2009) to infantile cues. People can retain infantile features into adulthood, giving them baby-faced features. These features include qualities such as

relatively large eyes, small chins, and large foreheads (Zebrowitz and Montepare 2006). The overgeneralization hypothesis holds that the psychological mechanism for infant care may overgeneralize and influence the impressions we form of adults with these baby-faced features in such a way as to facilitate interacting with these baby-faced individuals (Zebrowitz and Montepare 2006). Indeed, people do tend to think that those with infantile facial features are more trustworthy and interpersonally warm (Zebrowitz and Montepare 1992).

Additionally, although our current culture espouses the laudable value of treating all individuals equally, doing so in ancestral environments would have been risky. Indeed, mistakenly guessing that a person wants to harm us would have been far less detrimental to our survival (i.e., resulting in a potential missed opportunity, false positive) than would have mistakenly guessing that a person *does not* want to harm us (resulting in potential death, false negative; Schaller 2006). This may have created a selection pressure whereby people who did not successfully differentiate those who meant them ill from those who did not would have been more likely to encounter malicious actors. Therefore, mechanisms for differentiating between friends and foes would have been advantageous.

Evidence suggest that one such mechanism responds to cues of similarity. We lived in small, genetically related groups for the majority of our evolution (Tooby and Cosmides 2005; Kenrick 2011). Therefore, most of those likely to help us would have looked similar to us. A mechanism, which responded to cues of similarity with reactions that facilitate interaction, would have been beneficial. Indeed, work shows that people assume that similar-looking individuals are more trustworthy than are less similar-looking others (DeBruine 2005). For example, using photo-editing software, DeBruine modified images of participants' faces by creating composite images composed of those images of participants' faces and composite images composed of other, opposite-sex participants' faces, which DeBruine had collected in prior research. DeBruine then asked participants to make a series of forced

choices between pairs of composite images. Those self-similar images were randomly dispersed among the pairs of images between which participants had to decide. For each pair of images, DeBruine asked participants to choose the most trustworthy-looking face, the face that appears the most attractive for a long-term relationship, and the most attractive for a short-term relationship.

When asked to select the most trustworthy face, DeBruine found that participants were more likely to select the composites that included their own faces (i.e., similar to themselves) more often than they were to select the composites that did not include their own face. Interestingly, though, they did not choose the self-resembling image the most when selecting the face that they thought was most attractive as a long-term mate and were less likely to choose the self-resembling image when selecting the face they thought to be most attractive for a short-term mate.

In addition to identifying friends, additional mechanisms for identifying those that might wish us ill would have been advantageous. One such mechanism is thought to respond to cues of maleness with avoidance. For various reasons (see Daly and Wilson 1988), males have historically been more physically aggressive than women have been. For this reason, being leery of men would have yielded a net benefit. Again, being overly cautious with others might lead us to miss opportunities, but being overly gregarious with others, in a world without protections, might have resulted in our deaths. Therefore, given the wide sex difference in physical aggression, it would seem a safer bet to be cautious with unknown men. Indeed, work suggests that we have mechanisms that lead us to be leery in the presence of men. For instance, neutral male faces are interpreted as angry (an emotion often associate with aggression) more so than are neutral female faces (Becker et al. 2007), and, interestingly, androgynous angry faces are more often interpreted as being men than are androgynous happy faces (Kenrick 2011).

Outgroup members may have been another potential source of threat. Outgroups may not

always be hostile, but given the aforementioned costs of a false negatives (thinking someone intends no harm with they do; Schaller 2006), mechanisms for responding to cues of outgroup membership with caution and vigilance would have been advantageous. Indeed, we do appear to have mechanisms that respond in this way. We are more apt to misinterpret the neutral facial expressions of members of outgroups as angry, than we are to misinterpret the neutral facial expressions of in-group members (Becker et al. 2010). We also pay more attention to angry and threatening outgroup's faces (Ackerman et al. 2006).

Mechanisms for Avoiding Disease in Person Perception

Not all harm is intentional. We carry a host of biological passengers with us, and sometimes these passengers can be harmful to strangers. For example, many Native Americans became sick, and many died from exposure to the unseen biological passengers that Europeans brought with them. Pathogens have been an ever-present aspect of ancestral environments, and social living created one more avenue by which pathogens might find their way to us. For these reasons, a series of pathogen aversion mechanisms have been thought to respond to cues of pathogen exposure with a host of reactions designed to minimize our exposure to pathogen-carrying individuals.

Some evidence suggests that a series of pathogen avoidance mechanisms, collectively referred to as the behavioral immune system, reacts to cues of the potential presence of pathogens in others with aversion. For example, people report being less willing to get physically close (i.e., shaking hands and sitting closely) to those with visible signs of illness (Van Leeuwen and Petersen 2018). Other superficial features of poor health or signs of disease can also trigger these pathogen avoidance mechanisms. For example, the stigma against obese individuals and the elderly have been attributed to the pathogen avoidance mechanisms. Additionally, facial symmetry, a core feature of attractive faces, has been thought to be an indicator of one's ability to fight off infection

(Grammer and Thornhill 1994). Indeed, exposure to cues of potential pathogens leads people to prefer symmetrical faces to asymmetrical faces (Young et al. 2011).

Cues of pathogen presence also trigger the pathogen aversion mechanism leading us to avoid those from other groups. Disgust, an emotion thought to be elicited by cues of noxious stimuli in order to motivate avoiding exposure (Tybur et al. 2013), motivates people to avoid *unfamiliar* others. For example, those who are more apt to react to stimuli with disgust (i.e., greater disgust sensitivity) are more inclined to avoid unfamiliar outgroups (Aarøe et al. 2017). Therefore, when motivated to avoid disease, superficial features, such as cues of illness, poor health, poor resistance to health, or outgroup membership, can influence how people form negative impressions of *strangers*.

Perceptions of Romantic Intentions

In addition to identifying whether a stranger is a friend or foe, deciding whether a stranger might be a potential mate was an adaptive challenge faced by both males and females. Useful inferences people can make when identifying mates includes whether someone returns our interest and what type of mating arrangement they are pursuing. However, differences in the adaptive problems males and females have faced shaped different patterns of inference.

Given that men face the problem of parental certainty, missing a potential mating opportunity would be more detrimental (i.e., false negative) than mistaking disinterest for interest (i.e., false positive). When a potential mate does not reciprocate our interest, then no mating opportunity exists. Therefore, approaching an uninterested mate yields little change in one's current state, beyond the possible self-denigration that might ensue. No mating opportunity existed when a male approaches an uninterested mate, and no mating opportunity exists after the uninterested mate rejects the male. However, when a potential mate is interested, then a mating opportunity does exist. Therefore, failing to approach an interested mate does change one's current state. A mating opportunity did exist, but this opportunity may

evaporate when the male leaves without approaching the potential mate.

For these reasons, error management theory (Haselton and Buss 2000) suggests that male' mechanisms for identifying potential mates may be overly sensitive to cues of sexual interest. In terms of signal detection, they may have a liberal bias when searching for cues of sexual interest. Indeed, Haselton and Buss (2000) found this pattern. Specifically, when they asked men to estimate the extent to which a woman is sexually interested when they perform certain innocuous behaviors, they found that men overestimated how interested women were. That is, males formed impressions of female's romantic interest based on limited, superficial aspects of their behavior, and the nature of these impressions appear to have been shaped by the consequences of missing mating opportunities.

However, for the reasons discussed above, women have faced the problems of parental investment. Therefore, females face a different set of consequences than men do. Namely, misestimating a male's commitment could have left that female alone with the responsibility of rearing their child. For this reason, inferring commitment when it does not exist (false positive) would have been more detrimental than inferring no commitment when it does exist (false negative).

For these reasons, error management theory (Haselton and Buss 2000) suggests that female' mechanisms for identifying potential mates may be less sensitive to cues of commitment. That is, in terms of signal detection, they may have a conservative bias when searching for cues of commitment. Illustrating this pattern, Haselton and Buss gave women descriptions of the same innocuous behaviors they had shown men but attributed these behaviors to a man. They then asked women to judge the extent to which these innocuous behaviors indicated commitment. Haselton and Buss found that women underestimated men's commitment. That is, females formed impressions of males' romantic interest based on limited, superficial aspects of their behavior, and the nature of these impressions appear to have been shaped by the consequences of choosing uncommitted mates.

In the preceding discussion, we have reviewed how evolutionary reasoning has advanced our understanding of the way people interpret strangers' behavior. While evolutionary reasoning has shaped our understanding of other subjects studied in social psychology, we will refer the reader to some useful sources, such as the numerous chapters that have been written about evolutionary social psychology (Kenrick et al. 2015; Neuberg et al. 2010) and the textbooks and monographs written to review this work (Kenrick 2011; Schaller et al. 2014). However, before closing, we will turn to an important cautionary consideration for those interested in approaching the study of human social behavior with an evolutionary approach.

Important Considerations

Evolutionary reasoning has advanced our understanding of how selection pressures have shaped human social nature; however, evolutionary social psychology stands in a tenuous position given the nature of its subject matter and several common biases. Social psychologists study topics that are of great interest to the public and are often the topic of pundits, twitter users, bloggers, and other social commentators. Many of these social justice and civil liberty issues can be polarizing, even for social psychologists. Indeed, the field of social psychology is in the midst of some soul searching concerning these biases, as researchers have documented a bias within social psychology concerning these issues (Inbar and Lammers 2012). Although, our commitment, as scientists, to objectivity should overcome these biases, such that we would set aside our opinions and beliefs when conducting our research, evidence suggests that this has not happened (Conway et al. 2018).

Evolutionary social psychology has not escaped the consequences of this bias (Von Hippel and Buss 2017). The typical bias of traditional social psychology has led some of its participants to characterize the work of *evolutionary* social psychologists as having a bias that contradicts that of the rest of the field (Kenrick 2011). Indeed, certain anecdotal reports seem to suggest that

reviewers sometimes recommend rejecting manuscripts, which report evolutionary social psychology research that contradicts the prevailing bias of the field.

These biases may rely on at least two fundamental misunderstandings: the misunderstanding of the way nature and nurture operate together and the endorsement of the naturalistic fallacy. Researchers in the biological-based psychological fields now dismiss the nature-nurture dichotomy as being false. Instead, these researchers have come to the realization that biology and environment interact with one another, rather than contributing to behavior in an additive fashion. Therefore, the question of the extents to which behavior is a product of biology or environment is fallacious.

Further, beliefs driven by mistaken questions, such as these, are made even more problematic when accompanied by the naturalistic fallacy. The naturalistic fallacy is the misbelief that biologically based behaviors are good. That is, this assumption holds that that which is natural is good. This misbelief can lead to misunderstandings and misuse of evolutionary reasoning. Believing that biologically derived behaviors, or those that they mistakenly believe are the product of nature alone, are good may encourage people to identify biological bases for any behavior they support. On the other hand, the opposite may be true for behaviors, which people do not support. For these behaviors, people falling prey to the naturalistic fallacy may think of accepting evidence of any biological contribution as tantamount to justifying harmful or immoral behaviors. Though this is not the case, they may try to argue against and dismiss any evidence that suggests that those behaviors, which they do not support, have any biological contribution and thus resist any evidence they feel reveals such a contribution.

These same misunderstandings may lead scientists to misapply evolutionary reasoning. In their zeal to identify those behaviors they approve of as good and dismiss those behaviors which they do not approve of as bad, they may erroneously turn to evolutionary-like reasoning. Again, thinking that biologically based behaviors are good and

that, therefore, bad behaviors cannot be biological may lead people to seek ad hoc biological rationalizations for those behaviors they approve of. This type of reasoning is antithetical to the proper application of evolutionary reasoning. Evolutionary psychology begins by attempting to identify certain selection pressures that humans would have encountered across their evolutionary history by exploring the nature of human life in distantly ancestral times. Next, evolutionary psychologists attempt to identify what psychological algorithms (e.g., decision-making rules) might have helped early humans to overcome these selection pressures. Starting with a behavior and then looking for a selection pressure is the exact opposite approach. Therefore, while it may be tempting to look for reasons why those behaviors a person approves of might be “natural,” doing so is an exercise in poor science. Researchers interested in utilizing the evolutionary approach must necessarily keep these considerations in mind.

Conclusion

Evolutionary reasoning has yielded a number of theoretical advances in social psychology. Here we have focused on some of the major theoretical considerations employed when using an evolutionary approach, some of the contributions of these theoretical considerations to the study of person perception and important considerations for those new to the field to keep in mind. However, the contribution of evolutionary reasoning to the field goes far beyond that discussed here. When researchers can overcome the allure of the naturalistic fallacy and the misunderstanding of how nature and nurture interact, employing an evolutionary approach can bear a bounty of theoretical direction and insight.

Evolutionary Standards of Female Attractiveness

Elisabeth Oberzaucher

Universals in beauty

Definition

Aspects of female appearance that are linked to perceived attractiveness and/or biologically relevant information.

Introduction

Homo sapiens is the product of an evolutionary process. Evolutionary constraints shaped our bodies, perception, cognition, preferences, and behavior. The thus evolved characteristics are still present today. From a biological viewpoint, the ability to promote the own genetic information is central. This is why cues that are linked to reproductive potential are perceived as attractive.

Preferences for attractive features can be observed from early stages in life: Babies aged 2–6 months look longer at attractive faces. This “attractivism” continues to affect our lives

favoring attractive people in various contexts. Attractive pupils get better evaluations than their less attractive peers; the same holds true for students at University. In professional life, attractive people are more likely to be offered a job and higher wages. This clearly unfair treatment of people according to their physical attractiveness can be explained by our general preference for beautiful things that affects our actions on a sub-conscious level (Hamermesh 2011).

Given the major impact attractiveness has on our everyday lives, it is not surprising that a substantial number of research studies have attempted to identify and quantify characteristics linked to attractiveness. In general, those characteristics are not so much specific features but describe more general construction concepts.

The elements that have been identified as contributors to attractiveness allow for predictions about the biological fitness of the carrier and thus about the potential for successful reproduction. The face plays a prominent role in communication among humans and does so also for the assessment of attractiveness. So far, eight elements have been identified as the foundation of attractiveness.

Neoteny or Youthfulness

Neotenus features are described in Konrad Lorenz' Kindchenschema: The relative proportions of a large head, large round eyes, small stubby nose, and a large upper and small lower face are shared by young members of all mammal species. A small lower face and large eyes are perceived as attractive (Cunningham 1986). This as well as the preference for neotenus characteristics like lack of body hair, hair coloration, and skin texture point towards the role of youthfulness as attractiveness marker. Younger women have, on average, higher reproductive prospects. Therefore the preference for youth can be attributed to a tendency to maximize the reproductive outcome. Women, on the other hand, try to maintain a youthful appearance to improve their mate choice prospects (Jones et al. 1995).

Symmetry or the Lack of Fluctuating Asymmetries

Bilateral organisms usually deviate to some degree from perfect symmetry. There are two main types of asymmetries: (a) Directional asymmetry is common in all organisms and constitutes the phenomenon that one half is slightly smaller than the other. This directed asymmetry does not affect attractiveness but increases the memorability of stimuli – a small degree of directional asymmetry makes stimuli easier to recall than perfectly symmetric ones. (b) Fluctuating asymmetries are manifested through deviations from this main direction. The degree of fluctuating asymmetry is linked to developmental instabilities. An organism exposed to parasites, nutritional deficits, or environmental stressors will develop such fluctuating asymmetries. Thus, a lack of fluctuating asymmetries is an indicator of developmental stability, which could be due to favorable environmental conditions or an immune system that could handle the developmental challenges well. Indeed, a lack of fluctuating asymmetries increases the mate value in many species and is perceived as more attractive in humans (Thornhill and Gangestad 1993).

Averageness

Contrary to popular belief, averageness seems to increase attractiveness (Thornhill and Gangestad 1993). Composite faces generated by computer algorithms are perceived as more attractive than the faces used to generate this composite, on average. This avoidance of extremes holds true only for female attractiveness. In male faces, composites are less attractive than the original faces, which is likely due to less pronounced hormone markers, which leads to a less masculine appearance.

Skin Texture and Coloration

A homogenous skin texture without blotches and pimples is perceived as attractive, as irregularities

in skin texture indicate compromised health. Evenly distributed red coloration indicates peripheral blood circulation and is perceived as more attractive. During ovulation, peripheral blood is increased (Oberzaucher et al. 2012).

Hormone Markers

Hormone Markers are sex-specific characteristics that develop under the influence of sex hormones. Typically male hormone markers require high levels of testosterone during ontogeny, i.e., protruding eyebrow ridges and a robust and longer lower face. Estrogen leads to pronounced cheekbones and a generally more fragile facial structure. Besides enhancing sex-typicality these features boost attractiveness. The communicative function that is named most often is that high levels of sex hormones pose a developmental handicap. High levels of testosterone suppress immune response. Therefore the generation of hormone markers requires a delicate balance between testosterone levels on one hand and keeping the immune system functional on the other, in order to keep fluctuating asymmetries low.

Body Proportions

The body plays a more important role for female attractiveness than for male attractiveness. Some features seem to be strongly affected by cultural variation, such as the body mass index (BMI). These cultural differences could be due to differences in the socioecological conditions, i.e., in an environment with limited access to high-energy food, a higher BMI would be an indicator of sufficient energy availability and thus considered attractive. In most Western cultures, calories are abundant, and therefore a preference for lower BMI has manifested. The preference for a waist to hip ratio (WHR) around 0.7 seems to be culturally invariant. A lower WHR is linked to youthfulness and fertility. During menopause, the waist moves upward and the WHR approaches the value 1 (Singh and Young 1995).

The preference for long legs in female bodies is likely linked to accelerated longitudinal growth of extremities under favorable conditions.

Contrary to popular belief, breast size is not relevant for attribution of attractiveness. Breast size is – other than breast asymmetry – not linked to the ability to lactate.

Olfaction

Body odor plays an important role in mate selection: It informs about the immune system, nutritional, and health status. In women, the attractiveness of faces and body odor correlates (Rikowski and Grammer 1999).

Motion and Voice

Usually we do not perceive faces and bodies in static postures but in motion. Motion quality depends on the construction of the moving body. Physiological parameters affect the motion quality, modifying movement patterns over the female cycle.

Multiple Cues or Redundant Signaling?

The large number of cues that affect attractiveness could be due to two alternative communicative functions. The redundant signaling hypothesis postulates that the attractiveness of different body parts correlates highly (an attractive face is associated with an attractive voice, body, and body odor) – thus making these different cues merely parts of a redundant signaling system (Grammer et al. 2001).

Each cue could be responsible for communicating one specific aspect of biological fitness. If that were true, the computational effort required to assess the biological parameters would be rather high. This idea is supported by the association of different characteristics with different biologically relevant factors: Hormones, developmental stability, and life history affect organisms in specific ways that modulate different indicators of attractiveness.

Conclusion

In nonhuman animals, cues of attractiveness usually are indicators of reproductive potential. This seems to hold true for humans, too. Pflüger et al. (2012) showed that female attractiveness is indeed linked to a larger number of offspring. The facial shape corresponding to a larger number of children is characterized by a more gracile lower face, fuller lips, and larger eyes. A similar facial shape combined with enhanced redness of the skin corresponds to the form of ovulation (Oberzaucher et al. 2012). These facial features correspond closely to attractiveness ratings. This is the basis for the new hypothesis that facial attractiveness could have similar roots as the sexual swellings in apes, and as in apes, the biological function of sexual attraction is achieved through a proximate mechanism that boosts female attractiveness.

Definition

The causes of war remain a strangely obscure subject. While people have a good idea of the aims that may motivate states to go to war, an attempt at a strict definition of them is widely regarded as futile. This entry seeks to show how the various causes of violence and war all come together and are explained within an integrated human motivational complex, shaped by evolution and natural selection.

Introduction

The age-old philosophical and psychological inquiry into the nature of the basic human system of motivation is fundamental to the question of why people fight. Numerous lists of basic needs and desires have been put together over the centuries. The most recent ones show little if any marked progress over the older, such as Hobbes's insightful propositions in *Leviathan*, chapter 6. Such lists have always had something arbitrary and often trivial about them. They lacked a unifying regulatory rationale that would suggest why the various needs and desires came into being or how they related to one another. Thus, while Sigmund Freud claimed that the basic human drive was sexuality, Alfred Adler argued that it was in fact the striving for superiority, and Karl Jung emphasized the quest for creativity and whole being. There was no way of deciding, other than faith within what indeed became semi-religious sects, why it was this drive rather than the other that was the “truly” basic one or why in fact there should be a unitary basic drive at all.

Arguing that the human motivational system as a whole should be approached from the evolutionary perspective, we begin with an examination of the “human evolutionary state of nature,” the roughly 150,000 years, or more than 95% of *Homo sapiens*' evolutionary history, in which humans lived as hunter-gatherers. During this long stretch of time human natural predispositions were shaped. Once people developed agriculture some 10,000 years ago, which led to the growth of the first states about 5000 years ago, they set in

motion a continuous chain of developments that have taken us far away from our evolutionary natural way of life. However, cultural evolution has not operated on a clean slate nor has it been capable of producing simply anything. Its multifarious and diverse forms have been built on a clearly recognizable deep core of innate human propensities. Biologically, we are very much the same people as our Stone Age forefathers and are endowed with the same predispositions.

In contrast to long-held Rousseauian beliefs that reached their zenith in the 1960s, widespread deadly violence within species has been found to be the norm in nature, including among pre-agricultural hunter-gatherers (Keeley 1996; LeBlanc 2003; Gat 2006, 2015). The evidence from a whole range of hunter-gatherer societies reveals a staggering rate of violent fatalities: on average perhaps 15% of the adult population, 25% of the men, and all the surviving men were covered with scars. This rate is five to ten times higher than that of historical state societies.

At the same time and contrary to other fashionable 1960s notions, traced back to Freud's later-day theorizing, violence is not a primary, "irresistible" drive that requires release, like hunger or sex. The Swedes and Swiss, for example, have not fought for two centuries, yet they show no special signs of deprivation on this account. But try to deny them food or sex and their reaction would be quite predictable. On the other hand, the fact that violence is not a primary drive does not mean that we are not hardwired for it. People often make the mistake of assuming that violence must be either a primary drive or entirely learned, whereas in fact its potential is deeply ingrained in us as a tool ever ready to be employed. People can cooperate, peacefully compete, or use violence in order to achieve desired objects, depending on what they believe can serve them best in any given circumstances. They are biologically well equipped for pursuing each of these social strategies, with conflict being only one tool, albeit a major one – the hammer – in our behavioral toolkit.

Although we shall now go through the reasons for fighting one by one, it is not the intention here to provide yet another "laundry list" of separate

causes. Instead, the following seeks to show how the various "causes" come together in an integrated motivational complex, shaped by the logic of evolution and natural selection and its calculus of survival and reproduction.

Subsistence Resources

Subsistence resources are a prime cause of aggression and deadly violence in nature. The reason for this is that food, water, and, to a lesser degree, shelter against the elements are tremendous selection forces. As Darwin, following Malthus, explained, living organisms, including humans, tend to propagate rapidly. Their numbers are constrained and checked only by the limited resources of their particular ecological habitats and by all sort of competitors. Contrary to the Rousseauian imagination, humans, and animals, did not live in a state of primordial plenty. The specter of hunger and starvation was ever present. Affecting both mortality and reproduction, they constantly trimmed down population numbers. Thus, struggle over resources was very often evolutionarily cost-effective. Hunting and fishing territories were the main cause of conflict between human groups, as meat's nutritious value is the highest. Rich concentrations of fruit, roots, and seeds were also the object of competition and fighting. And in arid environments, water holes, critical for survival, were often a primary cause of conflict.

The benefits of fighting had to be matched against possible alternatives (other than starvation). One of them was to move elsewhere. This, of course, sometimes happened, especially if one's enemy was much stronger, but this strategy had clear limitations. By and large, there were no empty spaces for people to move to. In the first place, space is not even, and the best, most productive habitats were normally already taken. One could be forced out to less hospitable environments, which may also be already populated by other less fortunate people. Furthermore, a move meant leaving a habitat with whose resources and dangers the group's members were intimately familiar and travelling into uncharted environments. Such a change could involve heavy penalties. Finally, giving in to pressure from outside

might establish a pattern of victimization. Encouraged by its success, the alien group might repeat and even increase its pressure. Conflict is about deterrence; no less than it is about actual fighting.

Having discussed fighting's possible benefits and alternatives, deterrence brings us to its cost side. Conflict becomes an evolutionarily more attractive strategy for those who resort to it, the lower their risk of serious bodily harm and death. Consequently, displays of strength and threats of aggressive behavior are the most widely used weapons in conflict, both among animals and humans. Furthermore, when humans, and animals, resorted to deadly violence, they mostly did so under conditions in which the odds were greatly tilted in their favor. It is not the open battle but the raid and ambush – asymmetrical fighting – that constituted the principal and by far the most lethal form of “primitive warfare.”

The advent of agriculture, followed by state civilizations, changed human motivations that lead to fighting less than one may assume. Territories for cultivation (and for pasture) replaced hunting and foraging territories as an object for competition. But the real novelty brought about by cultivation was the exploitation of human labor. With cultivation, it became possible to live off of other people's work. Accumulated foodstuffs and livestock could be appropriated by looting. Furthermore, not only products but also the producers themselves could be captured and carried back home as slaves, to labor under direct control. Finally, looting could be further upgraded into tribute extraction, a more systematic and more efficient appropriation of labor and resources through political subjugation.

Sex and Reproduction

Together with subsistence resources, reproductive opportunities are the other major cause of fighting in nature. The anthropological evidence across the range of hunter-gatherer peoples tells the same story. Within the tribal groupings, women-related quarrels, violence, so-called blood feuds, and homicide were rife, often constituting the principal category of violence. Between groups, the picture was almost equally uniform. Warfare regularly involved the stealing of women, who were

then repeatedly raped by groups of men or taken for marriage, or both.

Both somatic and reproductive elements are intimately interconnected, for people must feed, find shelter, and protect themselves in order to reproduce successfully. Thus, conflict over resources was at least partly conflict over the ability to acquire and support women and children and to demonstrate that ability in advance, in order to rank worthy of the extra wives. Anthropological studies show that successful men in hunter-gatherer societies had several wives, in rare cases as many as a dozen, with a record of two dozen in the most productive environments. Many wives naturally meant a large number of children for a man, sometimes scores, who often comprised a large part of the next generation in the tribe (Chagnon 1979; Symons 1979; Keen 1982; Daly and Wilson 1983). Again, women are such a prominent motive for competition and conflict because reproductive opportunities are a very strong selective force indeed. This does not mean that people always consciously want to maximize their number of children. It is mainly the desire for sex – Malthus's “passion” – which functions in nature as the powerful biological mechanism for maximizing reproduction. As humans, and other living creatures, normally engage in sex throughout their fertile lives, they have a vast reproductive potential, which, before the introduction of effective contraception, mainly depended on resource availability for its realization.

Because of the asymmetry in their reproductive potential, men tend to be more polygamous than women and more competitive on that account. It has been shown that in all societies – from hunter-gatherer communities and tribal societies to medieval and modern nation-states – over 90% of all homicides are carried out by men, irrespective of the society's actual murder rate, which may vary greatly (Daly and Wilson 1988). Furthermore, the murder rate perpetrated by males peaks in both London and Detroit (although 40 times higher in the latter) at the age of 25 (Jones 1993). More mature males, already in possession of women and children, are “programmed” to adopt more conservative, safer, behavioral strategies.

The reproductive logic of human fighting remained in force also in state societies. Students of war scarcely think of sexuality as a motive for fighting. Nonetheless, throughout history, widespread rape by soldiers went hand in hand with looting as an inseparable part of military operations. Like looting, the prospect of sexual adventure was one of the main attractions of warlike operations that motivated people to join in. While in heroic sagas of semi-barbaric societies, such as the *Iliad*, the sexual value of that prize was barely veiled, the practice was no less in force – openly or more discretely – in the armed forces of more civilized societies (Thornhill and Palmer 2000; also Goldstein 2001). In modern imperial Japan, the troops still indulged in state-tolerated mass rape while serving abroad, some of it in the form of state-organized forced prostitution. At least two million women are estimated to have been raped by Soviet soldiers in conquered eastern Germany in 1945. Mass rape has been a major feature of the recent ethnic wars in Bosnia, Rwanda, Darfur, and West Africa. In the armies of the Western democracies, although rape is severely punished, American and other Allied troops widely availed themselves of an abundant supply of low-cost prostitution in ruined Western Europe after World War II and, later, in desperately poor Vietnam. In the opposite direction, the impact of sexuality on war has been demonstrated by the effects of the sexual revolution since the 1960s. By lessening the attraction of foreign adventure for recruits and far increasing the attraction of staying at home, it may have contributed to advanced societies' growing aversion to war. "Make love, not war," was the anti-war youth movement's slogan.

Fighting advanced reproductive success not only directly, as women were raped and kidnapped, but also indirectly, as the resources and status won by fighting advanced one in the intra-social competition for the acquisition and upkeep of women domestically. Where polygyny was permitted, the rich and powerful acquired a greater number of wives and enjoyed a marked advantage in choosing young, beautiful, and otherwise worthy ones. In addition to wives, many societies sanctioned official concubines, and there were, of course, unofficial concubines or

mistresses. Finally, there was the sex trade per se, where again the most consummate and graceful exponents of the trade could be highly expensive.

The manner in which power, wealth, and sexual opportunity were linked is most strikingly demonstrated at the apex the hierarchic pyramids. Rulers possessed large harems. According to the Greek authors, Alexander the Great captured 329 of King Darius III's concubines after the Battle of Issus (333 BC). According to the state records of China, the imperial harem of the Early Han (second and first centuries BC) comprised some 2000–3000 women, whereas that of the Later Han (first and second centuries AD) reached 5000–6000. The records of the Ottoman Privy Purse indicate that at its zenith, during the first half of the seventeenth century, the sultan's harem comprised some 400 women, with another 400 kept on a "retired list."

A remarkable study conducted on the Y (male) chromosome in Central and Eastern Asia demonstrates the great reproductive advantage gained by rulers (Zerjal et al. 2003). It reveals that some 8% of the population in the region (0.5% of the world's population) carry the same Y chromosome, which can only mean that they are the descendants of a single man. Furthermore, the biochemical patterns indicate that this man lived in Mongolia about a 1000 years ago. It was not difficult to identify the only likely candidate, Chinggis Khan, an identification confirmed by an examination of the Y chromosome of his known surviving descendants. This, of course, does not mean that Chinggis Khan alone sired so many children from a huge number of women, an obvious impossibility even if he had ceased his military conquests altogether. The tremendous spread of his Y chromosome is due to the fact that his sons succeeded him at the head of ruling houses throughout Central and East Asia for centuries, all enjoying staggering sexual opportunities.

Chinggis Khan was among the greatest warlords ever and his dynasty probably the most successful. Countless unsuccessful bidders for power, whose lines ceased because of their failures, have to be figured into the other side of the equation. Ruling was a high-stake – high-risk-

high-gain – affair, with force as its mainstay. The historical records of dynasties around the world show that the majority of rulers died violently. All the same, the apex of the social pyramid held such a powerful attraction for people because it was there that evolution-shaped human desires could be set loose and indulged on a gigantic scale. On a more modest scale, the same considerations held true further down the social hierarchy.

Status, Honor, and Prestige

From the interconnected competition over resources and reproduction, other causes and mechanisms arise. First, there is status in the group. Among all social animals, possessing higher rank in the group promises one a greater share in the communal resources, such as hunting spoils, and better access to females. For this reason, rank in the group is hotly contested. It is the strong, fierce, and – among our sophisticated cousins, the chimpanzees – also the “politically” astute that win status by the actual and implied use of force. Rivalry for rank and domination in nature is, then, a proximate means in the competition over resources and reproduction. For this reason, people jealously guard their honor. In traditional societies in particular, people were predisposed to go to great lengths in defense of their honor. The slightest offense could provoke violence.

Competition over rank and esteem could lead to violent conflict indirectly as well as directly. For instance, even in the simplest societies, people desired ornamental, ostentatious, and prestigious goods. Although these goods are sometimes lumped together with subsistence goods, their social function and significance are entirely different. Body and clothes ornamentation are designed to enhance physically desirable features that function everywhere in nature as cues for health, vigor, youth, and fertility. It is precisely these products of the “illusion industry” – cosmetics, fashion, and jewelry – that people everywhere spend so much money. Furthermore, where some ornaments are scarce and therefore precious, the very fact that one is able to afford them indicates wealth and success. Hence the source of what economist Thorstein Veblen called “conspicuous consumption,” in reference to the early

twentieth-century American society. In Stone Age societies as well, luxury goods, as well as the ostentatious consumption of ordinary ones, became in themselves objects of desire as symbols of social status. For this reason, people may fight for them. Indeed, while the consumption capacity of simple, subsistence products is inherently limited, that of more refined, lucrative ones is practically open-ended. One can simply move up the market.

Again, the potential for the fulfillment of the quest for honor and prestige increased exponentially in large-scale societies. The stelae on which autocrats celebrated their achievements in superhuman images are interpreted by scholars as instruments of royal propaganda, but, equally, they express the quest for the ultimate fulfillment of the craving for boundless glory and absolute domination, which could now be extended to the “four corners of the world” and “everything under the sun,” as the mightiest of imperial rulers boasted.

The same applied not only to rulers but also to political communities at large. Community members bathed in their collective glory and were willing to pay for its advancement and protection. Individuals and political communities jealously guarded their honor and responded forcefully even to slight infringements, not because of the trifle matters involved but because of the much more serious ones that might follow if they demonstrated weakness. To paraphrase Winston Churchill: choosing shame rather than war might very likely beget shame and then war.

Revenge

Revenge is one of the major causes of fighting cited in anthropological accounts of prestate societies. Violence was activated to avenge injuries to honor, property, women, and kin. If life was taken, revenge reached its peak, often leading to a vicious circle of death and counter-death. How is this risky and bloody behavior pattern to be explained? From the evolutionary perspective, revenge is retaliation that is intended either to destroy an enemy or to foster deterrence against him, as well as against other potential rivals. If one does not pay back an injury, one may signal

weakness and expose oneself to further injuries. A process of victimization might be created. This rationale applies wherever there is no higher authority that can be relied upon for protection, that is, in so-called anarchic systems. Thus, the instinctive desire to strike back is a basic emotional response which evolved precisely because individuals and groups who struck back were generally more successful in protecting their own. This is remarkably supported by the famous computerized game that found tit for tat the most effective strategy a player can adopt (Hamilton and Axelrod 1984).

However, tit for tat poses a problem. One's offender cannot always be eliminated. Furthermore, the offender has kin who will avenge him, and it is even more difficult to eliminate them as well. In many cases, tit for tat becomes a negative loop of retaliation and counterretaliation from which it is very hard to exit. One original offense may produce a pattern of prolonged hostility. Retaliation might produce escalation rather than annihilation or deterrence. Fighting seems to feed on, and perpetuate, itself, bearing a wholly disproportional relation to its "original" cause. People become locked into conflict against their wishes and best interests. It is this factor that has always given warfare an irrational appearance that seems to defy a purely utilitarian explanation. A prisoner's dilemma situation is created, producing vicious cycles of retribution and deadly violence. In the absence of an authority that can enforce mutually beneficial cooperation on people, or at least minimize their damages, the cycle of retaliation is often their only rational option, though, exposing them to very heavy costs; it is not their best option.

The prisoner's dilemma is of great relevance when explaining the war complex as a whole and not only that of revenge and retribution. Still, it ought to be emphasized that not all violent conflicts or acts of revenge fall under the special terms of the prisoner's dilemma. In the context of a fundamental resource scarcity, if one is able to eliminate, decisively weaken, or subdue the enemy and consequently reap most of the benefits, then this strategy is better for one's interests than a compromise.

Power and the Security Dilemma

The basic condition of competition and potential conflict, which gives rise to endemic suspicion and insecurity, invites not only reactive but also preemptive response, which further magnifies mutual suspicion and insecurity. Potential conflict can thus breed conflict. When the "other" must be regarded as a potential enemy, his very existence poses a threat, for he might suddenly attack 1 day. For this reason, one must take precautions and increase one's strength as much as possible. The other side faces a similar security problem and takes similar precautions. Thus, measures that one takes to increase one's security in an insecure world often decrease the other's security and vice versa.

What are the consequences of this "security dilemma"? In the first place, it tends to escalate arms races. Arms races between competitors take place throughout nature. Through natural selection, they produce faster cheetahs and gazelles, deer with longer antlers to fight one another, more devious parasites and viruses, and more immune "hosts." Many of these arms races involve very heavy costs to the organisms, which would not have been necessary if it were not for the competition. This, for example, is the reason why trees have trunks. Trees incur the enormous cost involved in growing trunks only because of their life-and-death struggle to outgrow other trees in order to get sunlight. As with humans, competition is most intense in environments of plenty, where more competitors can play and more resources be accumulated. This is why trees grow highest in the dense forests of the water-rich tropical and temperate climates.

Arms races often have paradoxical results. In many cases, every step on one side is matched by a counterstep on the other. Consequently, even though each side invests increasing resources in the conflict, neither gains an advantage. This is called, after one of Alice's puzzles in Lewis Carroll's *Through the Looking Glass*, the "Red Queen effect": both sides run faster and faster only to find themselves remaining in place. Arms races may thus become a prisoner's dilemma.

The special characteristic of the security dilemma is that its basic motivation on both

sides is defensive. Since suspicion is difficult to overcome, the sides may choose to actively preempt, that is, take not only defensive precautions but attack in order to eliminate or severely weaken the other side. Indeed, this option in itself makes the other side even more insecure, making the security dilemma more acute. Warfare can thus become a self-fulfilling prophecy. Since full security is difficult to achieve, history demonstrates that constant warfare can be waged, conquest carried afar, and power accumulated, all truly motivated by security concerns, “for defense.” Of course, in reality, motives are often mixed, with the security motive coexisting with a quest for gain.

With resource accumulation and hierarchic organization that became the norm in historical state societies, both resources and power could be accumulated and expanded on a hitherto unimaginable scale. Thus, power, like money, grew into a universal currency by which most objects of desire could be secured. For this reason, the quest for power seemingly acquired a life of its own and was also pursued for its own sake. At the minimum, the security dilemma in itself drove people and political communities to expand their power as a defensive measure.

Ideas and Identities

What about the world of culture? After all, it is our most distinctive mark as humans. Do not people kill and get killed for ideas and ideals? In the first place, people exhibit a marked, evolution-shaped predisposition to favor close kin, or those they perceive as close kin, over more remote kin, or “strangers,” that is, to favor those with whom they share more genes. As culture, particularly among hunter-gatherers, was local and thus closely correlated with kinship, cultural identity became a strong predictor of kinship. Moreover, culture sharing – most notably language, but also shared symbols, values, and customs – is also crucial for social cooperation, hence the phenomena of tribalism, ethnocentrism, and nationalism. Whether or not national communities are genetically related (and most of them are), they feel and function *as if* they were (Gat 2013). Independence from foreign domination has been perceived as

crucial to a people’s prosperity as a community of kinship and culture, often evoking most desperate expressions of communal devotion in its defense.

Furthermore, from the Stone Age on, the spiritual life of human communities was imbued with cultures that supported supernatural beliefs, sacred cults and rituals, and the practice of magic. The all-familiar glory of the gods, let alone missionary quests, never appear as reasons for hunter-gatherers’ warfare. The most regular supernatural reason cited by anthropologists for fighting among hunter-gatherers is fear and accusations of sorcery. It should be noted, however, that these did not appear randomly but were directed against people whom the victim of the alleged sorcery felt had reasons to want to harm him. This, of course, does not necessarily mean that they really did. What it does mean is that competition, potential conflict, animosity, and suspicion were conducive to fears and accusations of sorcery. To a greater degree than with the security dilemma, the paranoia here reflects the running amok of real, or potentially real, fears and insecurity, thus further exacerbating and escalating the war complex.

Finally, people everywhere kill and get killed over ideas – religious and secular ideologies – irrespective of kinship and across nations. How is this lofty sphere, often the most abstract of metaphysical ideas (all too often seemingly absurd notions), connected to the practicalities of life? The evolutionary status of religion is beyond our scope here. From Emile Durkheim (1965), functionalist theorists have argued that religion’s main role was in fostering social cohesion, inter alia in war. This idea has now been expressed in evolutionary terms (e.g., Wilson 2002). It means that in those groups in which common ritual and cult ceremonies were more intensive, social cooperation became more habitual and more strongly legitimized, which probably translated into an advantage in warfare.

Throughout history, religious and, later, secular ideologies have been interwoven with the other, more mundane, causes of war. Humans have a strong propensity for interpreting its surroundings as deep and as far as the mind can probe, so as to decipher their secrets and form a

mental map that would best help to cope with their hazards and opportunities. We have an innate, omnipresent, evolution-shaped predisposition for ordering the world, which inter alia extends to form the foundation of mythology, metaphysics, and science. We are compulsive meaning-seekers. Thus, the array of ideas regarding the fundamental structure and working of the cosmos and the means and practices required for securing its benevolent functioning have been largely perceived as *practical* questions of the utmost significance, evoking powerful emotions and motivation for action – including violence (e.g., Boyer 2001).

Conclusion

Conflict and fighting among humans, as in nature in general, is fundamentally caused by competition over scarce resources that are vital for survival and reproduction. While violence is evoked, and suppressed, by powerful emotional stimuli, it is not a primary, “irresistible” drive; it is a highly tuned, both innate and optional, evolution-shaped tactic or tool, turned on and off in response to changes in the calculus of survival and reproduction. Wars have been fought for the attainment of the same objects of desire that underlie the human motivational system in general – only by violent means, through the use of force.

Modernity, most notably its liberal path, has sharply reduced the prevalence of war (Gat 2006, 2017; Pinker 2011). The reason for this change is that the violent option for fulfilling human desires has become much less promising than the peaceful option of competitive cooperation. Furthermore, the more affluent and satiated the society and the more lavishly are people’s most pressing needs met, the lesser their incentives to take risks that might involve the loss of life and limb. People continue to compete vigorously over scarce objects of desire. However, the violent option, the “hammer,” in the human behavioral tool kit seems to have declined in utility for attaining desired aims, most notably within the world’s affluent and democratic areas, where war has all but disappeared.

Definition

There is a set of five values from which moral rules are derived: care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation. These values arise from a set of criteria laid out in the *Moral Foundations Theory*, which outlines theorized evolved foundations of moral behavior.

Introduction

For much of the history of psychology, beliefs around moral development were dominated by

the work of Kohlberg and Piaget (Donleavy 2008). They believed that morality was the result of a rational process and that as children developed they progressed across multiple stages of moral development. As children matured, it was argued that their morality became centered on ideas of justice and that these beliefs were the result of an internal dialogue processing facts logically. Unsatisfied with this explanation, Haidt (2001) proposed a counter model to moral beliefs, which he termed the *social intuitionist approach to morality*. This approach argues that instead of moral reactions being the product of logical thought, they are actually the result of emotional intuitions, later justified by gathering supporting data and ignoring conflicting information. Further research into this topic led Haidt and Joseph (2004) to refine the social intuitionist approach, producing a *model of evolved moral foundations*.

Haidt and Joseph (2004) proposed that humans possess multiple intuitive ethics, each of which evolved to navigate social situations. Through collaboration and cross-cultural work, Graham et al. (2013) proposed the current model used to explain moral foundations. *Moral Foundations Theory* rests on four claims: nativism, cultural learning, intuitionism, and pluralism. Once all of these claims are accepted, Graham et al. (2013) propose five moral foundations on which all moral development should rest: care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation.

Moral Foundations Theory

Within Moral Foundations Theory, *nativism* refers to the theory that the mind is developed before birth with prerecorded information (Graham et al. 2013). This means that the mind is organized before it can experience anything. To be clear, this does not mean that humans are immune to environmental influence but that nature provides a “first draft” of the mind. Moral Foundations Theory proposes that this first draft includes mechanisms designed to identify and record information relating to values, norms, and behaviors relevant to recurrent adaptive social problems. As these

problems are not equally important in every society, it is proposed that the types of information preferentially attended to should be based on cultural expectations.

Cultural learning refers to the process of editing the first draft of the mind. Depending on the requirements of a culture, the base modules included in the first draft of the mind will preferentially encode information relevant to that child’s culture, and this will be demonstrated through drastic differences later in life (Graham et al. 2013). For example, a woman in a highly conservative religious country will learn from an early age which scenarios allow for which specific behaviors, and in which scenarios those behaviors are prohibited. Developing this culturally specific knowledge may lead to her automatically initiating the proper behavior to show strong deference to authority. On the other side, most Western women will have vastly different experiences in childhood, and although they started with the same modules, their behavior later in life will be altered due to the cultural learning process. To further illustrate this point, Graham et al. (2013) use an analogy related to buildings; all humans start with the same moral foundation modules and they are shaped by cultural learning. This means that a culture can impact which of the moral foundations are built up, but it cannot create new moral foundations.

The third claim, *intuitionism*, states that intuitions about a situation arise first and the reasoning behind them come second. This was first applied to moral psychology in Haidt’s (2001) *Social Intuitionist Model*, which argues that moral judgments occur as the result of moral intuitions and that supporting evidence is found after a moral evaluation is made. This is most clearly seen in cases of moral dumbfounding. A common example of this is the following scenario:

A brother and sister want to feel closer together and decide to have sex. They tell no one what they have done, they use protection, and no harm was caused to anyone. After the fact both siblings feel closer to each other and are happy with their decision.

When presented this scenario, most participant will say what they did was morally wrong (intuition), but because the scenario is designed

in such a way that there is no logical justification for why what they did is wrong, participants will frequently come up with nonsensical answers (Haidt 2001).

The final claim of the moral foundations theory is *pluralism*. Pluralism states that throughout our evolved history, humans faced many recurrent social problems and that many social problems would require a moral foundation to overcome it. Graham et al. (2013) lay out five major adaptive problems our ancestors would have faced (i.e., care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation) and how these problems could have been solved through specific moral foundations. They then lay out how each of these foundations would have functioned compared to how they function today.

Moral Foundations

The care/harm foundation developed to promote the care of vulnerable offspring for extended periods of time. As human children are dependent for such an extended period of time compared to other mammals, and because they frequently require parenting from both parents, humans would have developed a mechanism to promote this care. The care/harm foundation developed to originally be triggered by visual and auditory signals of distress, neediness, or suffering by one's offspring. However, these triggers can be set off by other conceptually similar things, such as other children, animals, or cartoons, that share the proportions of children. The responses to these signals are frequently compassion for a victim and anger at a perpetrator (Graham et al. 2013).

The fairness/cheating foundation developed as a way to navigate cooperative social interactions. This foundation was originally triggered through observation or cooperation by a social partner or through gossip. However, current triggers can include inanimate objects, such as a vending machine, failing to produce a product when given money. The fairness/cheating foundation would have evolved such that those individuals who had a built-in module to detect cheating

would be less likely to be exploited compared to those who had to learn through trial and error. Responses to these signals are frequently anger at an exploiter, gratitude at a cooperator, and guilt for being an exploiter (Graham et al. 2013).

The loyalty/betrayal foundation developed as a way to facilitate coalitions. This foundation would have become especially important once intergroup competition between humans developed, as those tribes with stronger group cohesion would be more likely to succeed compared to less organized groups. Original triggers for this foundation would include large obstacles that an individual could not overcome or a joint enemy such as a rival tribe. Currently this foundation is frequently triggered by sports fandom and brand loyalty. Responses to these triggers include group pride and rage at traitors (Graham et al. 2013).

The authority/subversion foundation developed as a way to organize dominance hierarchies. As long as there were benefits associated with being able to scale the hierarchy, those individuals predisposed to understand how hierarchies operate would be more successful than those who had to learn as they went. Original triggers of this foundation are the presence of a social hierarchy in a social group. Recent triggers include the presence of governmental agencies, work place hierarchies, and familial hierarchies. Responses such as obedience, deference, and praise are associated with interacting with high authority figures, whereas failure to behave this way can cause outrage from both the authority figure and other subordinates (Graham et al. 2013).

The sanctity/degradation foundation developed as a way to minimize pathogen and parasite loads. Individuals who had to learn through trial and error that eating spoiled meat would lead to sickness would not survive as well as those with built-in disgust reactions. This foundation is frequently referred to as the behavioral immune system (Schaller and Park 2011). As this foundation operates as a pathogen avoidance system, there are few current triggers that were not potentially present in our ancestral environment. Such potential triggers include sexual deviance (sexually transmitted diseases), spoiled food (pathogen ingestion), and foreign groups (introduction of

new pathogens). The most frequent response to these triggers includes disgust and fear (Graham et al. 2013).

Although these are the current five major moral foundations, there are many more proposed foundations that do not meet the required criteria. To be classified as a moral foundation, the foundation must meet five criteria: concern in third-party judgments, automatic affective evaluations, culturally widespread, innately prepared, and adaptive advantage. For a review of other proposed foundations, see Graham et al.'s (2013) original article.

Moral Foundations Criteria

The first criterion of a moral foundation is that humans share a common concern in third-party normative judgments regarding the foundation. This is frequently referred to as a shared intentionality, or the ability for multiple people to hold a shared mental representation of what they are trying to do (e.g., Tomasello and Carpenter 2007). These shared representations exist because the idea is frequently transmitted between individuals through gossip. By frequently sharing gossip, individuals demonstrate a preoccupation with third-party violations and a concern that others will judge them based on these criteria. Therefore, if a potential moral foundation is rarely discussed in the same situations where other moral foundations are discussed, it likely does not warrant as a moral domain.

The second criterion of a moral foundation is the presence of automatic affective evaluations. As the moral foundations theory is an intuitionist theory, any moral foundations which are not the product of automatic process or are not emotionally charged do not meet criteria. This means if a moral response cannot be elicited easily or if a violation of a proposed moral foundation is not met with outrage, then it does not meet criteria.

The third criterion of a moral foundation is that it is culturally widespread. This simply means that if the moral foundation cannot be found in some basic form in most human cultures, then it does

not meet criteria. As moral foundations are evolved modules, their presence in human cultures should be near ubiquitous.

The fourth criterion of a moral foundation is the evidence of innate preparedness. As it is impossible to prove that a moral foundation is present in a culture due to an evolved mechanism versus the result of nondomain-specific intelligence, a moral foundation must demonstrate that it is present in either close relatives to humans, such as chimpanzees, or in children too young to have been subjected to learn the proposed foundation.

The final criterion of a moral foundation is that the moral foundation being proposed can demonstrate a clear adaptive advantage for humans who would have possessed such a trait compared to those who did not. In every moral foundation listed above, a clear adaptive benefit is presented to explain the presence of the moral foundation. If a moral foundation has no clear adaptive benefit, it is unlikely that it is an innate foundation as there would have been no selection pressure for it.

Conclusion

Relative to previous work on moral development, Graham et al. (2013) and others have demonstrated evolved moral foundations as the most likely explanation for the evolution and development of moral domains. This work has solidified five major moral foundations: care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation. However, there may be many more moral foundations yet to be discovered, and thus they lay out five criteria for the inclusion of additional moral foundations. This work helps explain previous research through an evolutionary perspective while opening up the possibility of future expansion of this theory.

Evolved Navigation Theory

Russell Jackson

University of Idaho, Moscow, ID, USA

Definition

Evolved navigation theory, or ENT, identifies how natural selection, acting on genetic variation related to navigational behaviors, shaped cognitive and locomotor mechanisms over evolutionary time.

Introduction

I proposed evolved navigation theory as a means to understand navigational behavior over evolutionary time (Jackson 2005; Jackson and Cormack 2007). This theory identifies that the

costs and risks of navigation to humans and other species pose strong sources of selection. Further, it outlines how cognitive and locomotor adaptations reflect this selection across a variety of behaviors. Evolved navigation theory investigations have discovered some of the largest scale phenomena in areas such as distance perception, motivation, and visual illusions. Understanding these themes is essential in order to understand how evolution shaped broad dimensions of behavior because navigation is prerequisite to most behaviors.

Natural selection acting on navigation takes many forms, as outlined by ENT. Energetic expense, exposure to predation, opportunity loss, and other environmental risks all select for specific navigational behaviors. Currently, the most well-explored source of such selection is the risk of falling.

Navigation and Cognitive Adaption Example: Falling

An often unrecognized source of natural selection in terrestrial navigation is the risk of falling. In modern contexts, falling is often the primary accidental source of injury and fatality in humans. Falling can be severe, but it is also visually predictable because it results from navigating vertical or sloped surfaces. ENT proposes a means for avoiding falls via a visual mechanism that already weights navigational decisions by costs: distance estimation. Humans, and likely most species, tend to pursue nearer navigational goals and avoid overestimated routes (Jackson 2013).

The above points predict that humans should overestimate the length of surfaces that are vertical in the environment. Although this idea directly contradicts mainstream theories of distance perception, it predicted exactly how we perceive such surfaces. People overestimate surfaces that are vertical in the environment, regardless of the surface's orientation on the retinae (Jackson and Cormack 2008; Jackson et al. 2013b). The average magnitude of this *environmental vertical illusion* is roughly equivalent to a person accurately

estimating the length of a school bus when such a distance is horizontal but estimating the height of a five-story building when that same distance is vertical.

From ENT, I also predicted that observers should estimate a surface differently if it poses different levels of risk. In fact, humans fall more often and to greater injury during descent than ascent. Thus, humans should overestimate the vertical extent of the same surface more while standing on top of it than while standing at its bottom. As predicted, human observers perceive greater vertical distance from the top than the bottom of the same vertical surface (Jackson 2005; Jackson and Cormack 2007). On average, people perceive a five-story building to be the equivalent of nine stories tall while standing on top of it. Compared to the method of calculating most distance illusions (5–15%), this previously unknown *descent illusion* is apparently the largest demonstrated in any species (nearly 90%). Whereas most illusions do not replicate across environment or culture, colleagues and I have found that the *descent illusion* replicates at identical magnitudes across groups that include isolated indigenous people of the Americas (Jackson and Gómez de García 2017; Jackson and Kizer 2017).

If falling risk over evolutionary time truly generated these illusions, then adding or subtracting evolutionarily relevant falling risks should induce or remove these illusions. Indeed, these illusions disappear when we remove such falling risks (Jackson and Cormack 2010) and appear when we add falling risks to surfaces otherwise perceived accurately (Jackson and Willey 2011, 2013). This work redefines acrophobia as a condition of altered spatial perception that produces a normal fear response, rather than its clinical definition as an abnormal fear of stimuli perceived normally (Jackson 2009). ENT research has investigated how these mechanisms are influenced by learning (Jackson et al. 2013b), navigational ability (Amiton et al. 2010, Willey and Jackson 2014), and exposure (Jackson et al. 2013a). These investigations also led to the discovery of one of the most powerful navigational algorithms, which can also quantify selection and behavioral motivation across species (Jackson 2013).

Conclusion

ENT illusions are not small effects occurring only in contrived environments; they are among the largest magnitude phenomena in their respective areas and they occur ubiquitously in everyday vision. Participants in these studies are unaware that their estimates are wildly inaccurate or that they are being tested for falling risk, even when asked explicitly. These illusions are robust across environment, method, and culture and have been replicated in competing labs. Prior to this research, these mechanisms were unknown and yet they are a primary predictor of a broad source of mortality – both in the environments in which we evolved and in the modern world.

Evolved Physiological Reactions

Andreas Olsson and Irem Undeger
Department of Clinical Neuroscience, Karolinska
Institute, Stockholm, Sweden

Synonyms

Fight-or-flight; Physiology; Systems; Threat responses

Definition

Species-specific physiological reactions have evolved in response to evolutionarily stable opportunities and challenges. Many of these responses are conserved across species and can be studied in humans as sets of interrelated, and coordinated, physiological reactions to stimuli with intrinsic and/or learned values.

Introduction

The survival of a species relies on multiple motivational factors: appetitive, defensive, and reproductive. In mammals, each of these factors are characterized by specific patterns of physiological reactions designed to cope with challenges and opportunities in the environment. Research has described physiological profiles of a variety of motivational states, ranging from basic avoidance of predators and defense against threatening conspecifics (Blanchard and Blanchard 1990) to complex social states, such as deception (de Waal 1992) and empathy (Zaki 2014). Avoiding threats and, at the same time, maintaining opportunities for foraging and mating constitute strong environmental constraints that have favored the selection of physiological reactions that facilitate the detection of, responding to, and learning about, salient cues in the environment. The particular set of activated physiological reactions to, for example, threat and reward cues vary across species as a function of the evolutionary constraints operating on the species habitat. In addition to ecology-dependent variation between species, individuals within each taxon vary considerably in their physiological response profile. In humans, extreme physiological reactions to threat and reward cues constitute the bases for common psychiatric disorders.

In humans, the autonomic part of the nervous system coordinates a host of physiological responses that have evolved to cope with opportunities and challenges in the environment. In this entry, we focus on a series of physiological reactions to threat that have been extensively studied and described: endocrine, cardiovascular, pupillary, electrodermal, and respiratory. In the following, each of these evolved reactions will be briefly described together with their known key brain correlates.

Physiological Reactions to Stress and Reward

Physiological responses of an organism aid in survival, optimizing the trade-off between possible rewards and threats present in the surrounding.

Mammals react to the presence of a threat, such as a predator, by reduced heart rate and immobilization (Mobbs et al. 2015). Other immediate reactions, among them enhanced orienting and arousal (Öhman 1986), increase the chances of survival by facilitating information processing and preparation for action. At any given moment, an animal must strike a balance between exploring possible resources and avoiding being attacked. The choice between passive and active coping strategies in the face of threat is regulated by its proximity (Mobbs et al. 2015). If escape is possible or fight is an option, the prey prepares for active coping. The fight-or-flight response has evolved to aid escaping and fighting the aggressor, and is therefore characterized by specific physiological changes to support this, such as an increasing blood flow, which supplies the muscles with energy. In turn, and as a part of the ongoing arms race between prey and predators, predator physiology is designed to maximize its chances of catching the prey by increasing mobility and readiness for action. The behavioral principles governing these decision processes across species have been discussed extensively in behavioral ecology (Stephens and Krebs 1986). Freezing, on the other hand, is a passive coping strategy and is used when escape is not possible or in immediate proximity to the predator. This state allows the animal to both avoid detection and assess defense strategies. For example, flight behavior can be initiated while freezing.

In the laboratory, researchers have predominantly used Pavlovian fear conditioning procedures to study reactions to threat (LeDoux 2012). During Pavlovian conditioning, an emotionally neutral stimulus (CS) is repeatedly paired with a naturally aversive unconditioned stimulus (US), such as an electrical shock. As a result of this pairing, the CS elicits an enhanced orienting toward the stimulus, and a slew of defensive responses, such as freezing and autonomic arousal (Lang and Davis 2006). In many social species, threat information is transmitted efficiently between individuals, offering a more safe learning strategy as compared to individual trial and error learning (Laland 2004). Social learning about threats is supported by partly the same

physiological responses as Pavlovian fear conditioning (Olsson and Phelps 2007).

The emotional value of threats and rewards can be described along two key dimensions: (1) valence and (2) arousal, each one linked to partially different physiological response profile. Valence varies from negative to positive, whereas arousal ranges from low to high. In humans, the arousal component is commonly measured through autonomic activity, which can be quantified by, for example, changes in electrodermal activity (sweat production on the surface of the skin). Valence is commonly measured through the potentiation of the basic, brain-stem mediated, startle reflex, to sudden sensory stimuli (Lang and Davis 2006). This response can be measured across species and is therefore relatively well described in terms of its neural bases. Human research often uses electromyography (EMG) to record the amplitude of the eye-blink startle reflex in response to external stimuli. In comparison to a neutral baseline, aversive stimuli potentiate, and rewarding stimuli augment, the startle reflex.

Not only must the individual respond immediately to threats and opportunities. The value of past experiences should also be used to predict future encounters. Physiological responses have therefore evolved to facilitate the encoding of, for example, threats, thereby optimizing behavioral responses. Indeed, emotional arousal improves memory (McGaugh 2002), constituting an adaptive physiological function that has been preserved across many species. Human and animal studies have highlighted the hippocampus as the key region for declarative memory formation in the brain (Kim et al. 2015). The amygdala, which is located in close proximity to the hippocampus, is thought to facilitate plasticity in hippocampal regions, thereby promoting learning of emotionally salient information for future use. The amygdala promotes learning indirectly through modulating memory formation in different regions of the brain, such as the hippocampus (McGaugh 2002), and directly, through acquiring, storing, and expressing learned threat responses (LeDoux 2012).

Two parts of the peripheral nervous system orchestrate human physiological reactions: the

somatic and the autonomic. The somatic nervous system consists of motor nerves, responsible for voluntary muscle control from the central nervous system (CNS) to the body and sensory nerves that are responsible for perception of external stimuli from the sensory organs and the environment to the CNS. The autonomic nervous system (ANS) coordinates the physiological reactions. These bodily responses are to a large extent not under voluntarily control and are unleashed before a behavior is performed to prepare for its execution.

The ANS controls human physiology through its two parts: the sympathetic nervous system (SNS) and the parasympathetic nervous system. Generally, these two systems work in opposition to each other. For example, the parasympathetic nervous system activity antagonizes the SNS and the body enters into relaxation (e.g., heart rate and digestion reduces) and restoration. The detection of, and learning about, threats are regulated by a combination of different physiological pathways in many different organs and tissues: the endocrine, the cardiovascular, the pupillary, the electrodermal, and the respiratory. Each of these subsystems will be briefly described below in relationship to their evolved functions and associated key brain structures that are involved in creating these responses.

The Endocrine System

The endocrine system consists of the glands distributed in an organism that secrete hormones in order to regulate physiology and behavior. Hormones are secreted into the circulatory system, allowing different organs to communicate with each other. Apart from maintaining homeostasis, hormones are responsible for creating responses to internal and external stimuli.

The hypothalamus links the nervous system, from which information about external stimuli is acquired, to the endocrine system through the pituitary gland. Together, hypothalamus and the pituitary glands are part of a larger complex called the hypothalamic-pituitary-adrenal (HPA) axis, which controls a range of states from sleep to stress. The main hormones that are secreted by

the glands of the HPA-axis are glucocorticoids (“cortisol” in humans), the so-called stress hormone, through adrenal glands. Stress can be defined as a state, which systems adopt when facing a threat to the homeostatic balance. This threat can be a direct threat to the physical integrity of the individual, such as the presence of a predator, or of psychological kind, such as the perceived harmfulness of getting bankrupt. Glucocorticoids influence behavior through regulating neural pathways that facilitate or hinder certain behavior, depending on when they are released: before, during, or after encountering the stressor.

The onset of the stress response depends on the environmental conditions and the learning history of the organism. As mentioned earlier, the state of arousal resulting from the presence of threat augment learning, and a key structure is the hippocampus. The hippocampus is densely populated by glucocorticoid receptors (Kim et al. 2015). Mild stress has a transient effect and leads to changes in memory, yet strong and chronic levels can lead to permanent morphological changes (Conrad 2008). While it is important to remember sources of threat for survival, severe, and long-term stress leading to such permanent changes can create to unwanted outcomes, such as in the case of posttraumatic stress disorder (PTSD) (Kim et al. 2015).

The activation of the SNS is faster than the secretion of cortisol in response to threat, mediating the immediate responses. Noradrenaline (NA or norepinephrine) is secreted by the adrenal medulla and reaches the blood stream as a hormone during fight-or-flight and freezing responses and mediates metabolic effects such as an increase in glucose and free fatty acids in blood. NA is also activated in the brain as a neurotransmitter and facilitates Pavlovian fear learning through long-term potentiation (LTP) in the amygdala (Weinberger et al. 1984). SNS activation also lead to the activation of the HPA, which results in an increase in cortisol levels, highlighting the interplay of fast nervous system and slow hormonal responses in the face of threat. NA has both central and peripheral effects, on the sensory organs NA acts as a neurotransmitter that leads to a plethora of events such as pupil dilation,

increased heart rate, and increased blood flow to large muscles (Fig. 1).

The Cardiovascular System

The cardiovascular system is responsible for distributing oxygen and energy throughout the body. Blood flow is regulated by the demand for oxygen in active tissues, and the rate of delivery is the product of heart rate and blood pressure. Heart rate and blood flow are controlled by many factors, such as hormones and the autonomic nervous system. In times of stress, for example during fight-or-flight responses, cardiac output, respiration, and blood flow increase in response to the NA released from the SNS. During this active strategy, the amygdala mediates the changes in cardiac and respiratory outputs (Cacioppo et al. 2007). Increase in heart rate and blood flow to

large muscles aids in survival by meeting the metabolic needs of the animal when flight is the best behavioral strategy.

In the case of a passive coping strategy, heart rate slows down. Decrease of heart-rate, *fear bradycardia*, has been associated with freezing in animal studies, including humans (Lang and Davis 2006). Immobilizing decreases the chances of being detected by the predator, increasing the chances of survival. Humans vary to the extent with which their heart rates are changed in response to fear conditioning; low heart rate variability is commonly believed to be a precursor for higher responses in fear-potentiated startle (Hamm and Weike 2005).

The Pupillary System

The diameter of the pupil regulates how much light enters the eye and is controlled by two

Evolved Physiological Reactions, Fig. 1 When exposed to a threat, the amygdala starts a signaling cascade. This results in engaging the HPA-axis, which results in cortisol release, and sensory nervous system (SNS) innervation, leading to the secretion of noradrenaline (NA).

Cortisol has memory enhancing effects. NA can act either in the brain as a neurotransmitter, and upon secretion causes a plethora of physiological reactions (*middle box*) or on sensory organs causing behavioral reactions (*right box*) in the latter

muscles: sphincter and dilator pupillae, which are under the control of ANS. Pupil dilation does not only occur in low light conditions, but has been found to reflect cognitive and emotional processes. Pupils dilate more to emotional words (Siegle et al. 2003), auditory stimuli (Partala and Surakka 2003), and pictures (Bradley et al. 2008) than to neutral ones. The evolutionary advantage of dilated pupils is still debated, but one prominent idea is that increased light allows better vision in dark environments.

The dependence on other individuals and the group has been an important factor during primate evolution. This dependence is likely to have selected for various abilities to detect and respond to conspecifics' intentions, emotions, and trustworthiness. Pupil size, along with characteristics such as facial expressions, is a social cue used to predict others' behaviors by ascribing intentions and emotions to them. For example, exposure to large vs. small pupils activates the amygdala (Harrison et al. 2006), which regulates the arousal system, and helps preparing for defensive responses (see above). More complex social behaviors, such as in-group trust, have been linked to mimicry of the pupil. For example, partners with dilated pupils are generally more trusted than those with constricted pupils (Kret et al. 2015).

The Electrodermal System

One of the most widely used psychophysiological reactions used in human research on basic affective and survival responses is electrodermal activity (EDA). ANS regulates sweating through sweat glands: the eccrine sweat glands cover most of the body and are more concentrated on the palms and soles of the feet; and the apocrine sweat glands are located in the armpits and the genital areas.

Most researchers study the skin conductance property of the EDA, which measures the skin resistance or conductance. Tonic level of skin conductance is referred to as skin conductance level (SCL), whereas phasic changes overlapping with the tonic response is referred to as skin conductance response (SCR). In a laboratory setting, changes in EDA can be the signal of different

level of activation of the SNS: sensory input, expectation/preparedness, increased attention, and arousal (Boucsein 1992). Along with interindividual variability in ANS responses, variations in SCR between individuals are related to differences in personality (e.g., introversion/extraversion) and psychopathology (e.g., anxiety disorders) (Boucsein 1992).

Many studies investigating threat responses report an increase in SCR and SCL in response to stimuli associated with threatening, compared to "safe," stimuli. Pavlovian fear learning paradigms have shed light on mechanisms of threat learning and extinction learning (the updating of threat value when the CS is no longer dangerous (e.g., Phelps et al. 2004). Learning each and every threat source is inefficient for the organism, thus generalizing the threat information to an extent would be optimal for survival. SCR to stimuli from the same category as the CS+ do not need to be specifically conditioned in humans, generalization occurs most readily between typical members of categories and less between atypical ones (Dymond et al. 2015). Overgeneralization, however, is a characteristic of certain psychopathologies (i.e., PTSD, panic disorders and specific phobias) (Dunsmoor and Murphy 2015). Just as in the case of enhancement of memory upon stress (see above), this highlights how an adaptive physiological mechanism can become dysfunctional in its extreme cases.

The Respiratory System

The respiratory system provides the oxygen for the organism that is needed to carry out metabolic processes that create energy in cells. The respiratory system is closely linked to the cardiovascular system: variance in depth or rate of breathing affects heart rate. As heart rate in turn controls blood flow, thus the rate at which oxygen travels to required tissues is controlled by both respiratory and cardiovascular systems. Rate of respiration is controlled by the ANS and has therefore been used in research to investigate ANS activation, complementary to other physiological measures mentioned above (e.g.,

heart rate, SCR). When faced with threat, cardiac acceleration is accompanied by faster breathing, dilation of the airways (bronchioles), decrease in respiratory volume, and thus a decrease in blood CO₂ levels (Kreibig et al. 2007) as the body gets ready for defense. Metabolic needs of the organism are met in the face of threat, allowing a successful flight or fight. Relief from threat decreases the respiratory activity and increases sigh frequency (Blechert et al. 2006).

The Motor System

When the threat is perceived and an appropriate response is initiated, it is the skelomotor system's responsibility to enact any of the three basic behavioral responses; freezing, fleeing, or fighting. The startle response is defined as a series of rapid muscle movements throughout the whole body, in the face of an abrupt sensory input. In many animals, this facilitates escape (e.g., the whole body startle in mice), but it might also function to protect the organs. For instance, the eye-blink startle reflex causes a blink, which serves to protect the eye from damage. Mammals under threat elicit stronger startle reflexes, due to the state of arousal, which is also reflected in greater amygdala activation (Lang and Davis 2006).

A great part of nonverbal communication in humans and other primates involves facial expressions. Correctly interpreting, and responding to, others' facial expressions is crucial for both successful social interactions and survival. In humans, six basic facial expressions have been identified to represent emotional states and assumed to have a universal meaning: happy, sad, fear, anger, surprise, and disgust (Ekman et al. 1983). Based on lacking support of neural activities corresponding to discrete emotional labels, recent researchers have emphasized the dimensional approach to emotions (Lindquist et al. 2012). The response of the ANS to perceiving facial emotional expressions is sensitive to the valence of the emotion and can distinguish among negative emotions (i.e., between anger, fear, disgust, and sadness).

Conclusion

Many physiological reactions have clear evolutionary advantages in the face of environmental opportunities or challenges. Internal physiological and environmental cues support the individual's choice between different survival and foraging strategies, allowing the organism to behave adaptively and thus increasing its chances of survival. To this aim, different systems work in concert under the control of the nervous system. In this entry, we have described a selection of integrated physiological reactions, their survival functions, and associated key neurobiological bases.

Evolved psychology; Predictors of violent intergroup conflict; Theories

Definition

Psychological processes involved in aggressive collective actions of groups toward other groups, typically characterized by high levels of destruction and mortality.

Introduction

Intergroup violence and warfare can have different forms. In raids, attackers significantly outnumber their opponents, whereas battles involve roughly equal numbers of combatants on both sides. Among traditional small-scale societies, battles occur less often than raids and are often ritualized, nonlethal encounters. In modern societies' war history, however, there are countless examples of lethal large-scale intergroup encounters, like the Battle of Stalingrad, which caused more than two million military and civilian casualties. This battle was part of the deadliest war of human history, World War II from 1939 to 1945, with more than 60 million deaths overall. Violence between groups remains omnipresent today, causing about 180 thousand deaths in 2014, let alone massive destructions of infrastructure and the ecosystem, as well as large-scale emigration from warzones.

It has repeatedly been argued that violent intergroup conflict may have played a major role in our ancestral past and that the selective pressure it exerted may even have been so intense to actually have shaped our cognitive mechanisms (Bowles 2009; Choi and Bowles 2007). In fact, today many archeologists and evolutionary anthropologists agree that warfare has steadily accompanied human prehistory and that deadly fighting between groups was far more common than within groups (e.g., Keeley 1997).

Although the absolute numbers of casualties of modern wars certainly exceed those of intergroup conflicts within and between more traditional societies by a great margin, relative to population size, current wars can be argued to be relatively petty (Pinker 2011). The available data on war casualties in traditional societies, though, suggests

that war was a much more important source of adult mortality in our ancestral past. For societies in which war was present, estimates of (male) adult mortality due to intergroup violence range from around 10 % to more than 50 % (Bowles 2009; Keeley 1997). Consequently, several theories of an adaptive psychology of warfare have been proposed.

Theoretical Perspectives on Warfare

War requires collective action. The potential benefits of victorious intergroup conflicts are often shared quite equally among members of the winning group, whereas individual fighters incur the costs and hazards of participation in combat like injury and death. Accordingly, warfare has been argued to constitute a within-group social dilemma, in which conflict participation is a cooperative action toward the own group. Theories of parochial altruism use group selection models to explain human warfare (Bowles 2009; Choi and Bowles 2007). Their basic assumption is that the willingness to aggress against other groups at personal cost is an act of true altruism toward the own group. Computer simulations based on rather specific assumptions about population structure, group interactions, and the costs and benefits of war support the hypothesis that altruism toward members of the own group and parochialism, i.e., disregard or even aggressiveness toward members of other groups, may have coevolved and eventually spread in the meta-population (for a detailed review, see Rusch 2014). Furthermore, warfare requires sophisticated cognition in order to correctly determine group memberships but also to detect and sanction noncooperators within the own group.

Other scholars reject population genetic explanations of warfare (for an overview, see van der Dennen 2002). They propose that war is a cultural phenomenon. One of its functions, for instance, may be the regulation of population size (man/land ratio). Cultural group selection models represent an integration of these opposing perspectives (for an overview, see Richerson

et al. 2016). According to this view, genetic group selection may not be sufficient to explain intergroup violence when group sizes exceed a few dozen individuals and migration between groups becomes larger. Instead, these authors propose that genes and culturally transmitted traits interact in forming our psychology of war. More specifically, they claim that while our readiness to learn and to obey social norms likely is genetically hardwired, this only leads to violent intergroup conflict where social norms promote such aggression. Eventually, these social norms may then have spread, because they gave aggressive cultures an advantage over more peaceful groups.

Empirical Evidence

Complementary to theoretical accounts of human warfare, there is plenty of empirical evidence collected by various disciplines on the different forms of and motivations for participation in violent intergroup conflict. Evidence is accumulating, for example, that collective action to the benefit of the own group in the presence of competing other groups is greater than in single-group social dilemmas (for an overview, see Benard and Doan 2011). This supports the notion that within-group cooperation is linked to intergroup competition.

However, when individuals can choose between peaceful within-group cooperation and aggressive between-group conflict, the available evidence is less conclusive. Therefore, several moderating factors have been suggested. For instance, theoretical and empirical research has shown that the motivation to participate in aggressive intergroup interactions is larger if individuals perceive their own group in a defensive rather than offensive position (e.g., Böhm et al. 2016). Moreover, there is theoretical and empirical evidence that increased reproductive access to women is an important driver of male participation in conflicts. Hence, men may be more likely to participate in warfare in order to obtain additional

reproductive access to out-group females and increased attention of in-group women (McDonald et al. 2012).

Conclusion

Warfare is a frequent phenomenon among humans. Explanations for its occurrence based on natural selection, cultural evolution, and combinations of both exist in the literature. Empirical evidence suggests that there are important structural factors and individual differences affecting the motivation to participate in warfare, including offensive versus defensive conflict objectives and gender.

Synonyms

Multilevel selection theory

Definition

Cases of behavioral traits among groups of animals that were naturally selected at the group level instead of the individual or genetic level.

Introduction

Group selectionists argue that specific traits may have been positively selected because they aid in the survival of groups as opposed to enhancing the survival of the individual or gene. In other words, individuals within the group may incur a cost that eliminates their survival and/or reproduction, but the group as a whole continues to survive and reproduce. Although group selection is a controversial theory in evolutionary biology, supporters of this theory have presented many examples as corroborating evidence. This entry discusses some of these examples that group selectionists have discovered.

Group Selection

Although natural selection at the level of the individual may favor selfish behaviors, some argue that natural selection at the level of the group may favor cooperative behaviors (Nowak 2006; Nowak et al. 2010; Seeley 1997). Groups of cooperators will survive and reproduce more successfully than groups of selfish individuals (Nowak 2006). Group selection has been applied to explain a myriad of behaviors across many species and biological levels. For instance, some have argued that group selection may account for the development of cooperative behaviors within multicellular organisms (an individual cell inside a person's body does not act selfishly but acts cooperatively to help sustain the overall body) (Nowak 2006).

Many other examples of group selection stem from eusocial insect societies, such as ants and honeybees. Eusociality refers to very organized cooperative behaviors among individuals in a group, often in which an individual will forego his/her own reproductive opportunities for the sake of the group (see Nowak et al. 2010, for a review). For example, researchers have recently found that army ants will connect their bodies with each other to form bridges, which allow the other ants in the colony to cross gaps and areas of water (Reid et al. 2015). This is a useful tactic that allows the rest of the group to find a food source or

escape a predator. This coordinated action often results in the death of some of the ants that form the bridge, but the rest of the colony is able to survive and eventually reproduce.

Seeley (1997) proposed, and empirically tested, a mathematical model that supported the group selection of honeybee colonies. In particular, the bees that forage for nectar will engage in a particular dance – a waggle dance – that communicates to the hive to activate more nectar foragers, but this dance is only utilized when the entire hive's rate of nectar collection is low. Engaging in this dance does not grant the bee any direct benefit but increases the nectar collection of the hive as a whole – allowing for the enhanced survival of the entire colony.

There has been considerable debate over whether group selection theory accounts for certain mammalian behavioral traits – such as alarm calls in ground squirrels and meerkat sentinels – in which one individual will emit a loud sound to alert the others within the group that a predator is near (Clutton-Brock et al. 1999). These individuals incur a potential cost (e.g., an increased probability of being noticed, chased, and eaten by the predator) for the rest of the group to benefit. It is important to note that alternative explanations regarding nepotism and reciprocity may also account for these cooperative behaviors.

Although examples of group selection are often applied to eusocial insects and nonhuman mammals, some psychologists have argued that group selection may apply, on a cultural level, to humans as well. Humans in large-scale groups benefit because of the cooperation that occurs for the acquisition of public goods. Public goods refer to resources that are accrued at a cost to each individual, but benefit the overall group, such as paying taxes, contributing to charities, and conserving/defending natural resources. In order to maintain this cooperation for public goods, altruistic punishment toward those who do not contribute to the public good is utilized. Altruistic punishment refers to having a third party enact a negative consequence upon an individual who has violated a social norm (e.g., committed a crime, did not contribute to the overall

public good, or engaged in a behavior that is deemed negative).

Altruistic punishment is a cultural phenomenon that is argued to be best explained by group selection (Boyd et al. 2003; Rebers and Koopmans 2012). Imagine an individual evades paying his/her taxes and is then prosecuted for this crime. No individual citizen within the group gains any benefit from the tax evader's punishment, but the punishment promotes the successful survival of the group (or society) by obtaining the public goods (e.g., taxes) and enhancing the cooperative behaviors of the other individuals in the group by illustrating a deterrent. Empirical data suggests that groups who engage in altruistic punishment also possess higher levels of cooperation (Fehr and Fischbacher 2003).

Conclusion

Group selectionists view these examples of cooperative behaviors within different groups and species as evidence that natural selection does not necessarily have to occur at only the individual or genetic level. It is possible that, in some cases, natural selection may influence the survival and reproduction of groups as a whole, rather than influencing the survival and reproduction of each individual within the group. However, it is important to note that critics of group selection posit many alternative explanations – such as inclusive fitness theory (Hamilton 1964) and reciprocal altruism theory (Trivers 1971) – with supportive empirical evidence that may also account for these cooperative behaviors within groups. The debate over whether group selection adequately accounts for cooperative group behaviors will continue when examples such as these are discovered.

Definition

Pair bonding is a term used in biology to indicate a strong interindividual relationship within breeding pairs most often consisting of a male and a female. The term is closely related to social monogamy, a mating system based on long-lasting relationships between sexual partners. Social monogamy differs from sexual monogamy in that it does not imply sexual exclusivity.

Introduction

Males and females from sexually monogamous species pair to mate and procreate exclusively with each other, whereas socially monogamous (pair-bonded) males and females share a territory, mate and take care of the offspring together, but also engage in extra-pair copulations on occasion. Strict sexual monogamy is rare in nature. Social monogamy is however more common, and the prevalence of this mating system differs remarkably across different groups of the animal kingdom. For example, monogamy is rare in fish, amphibians, and reptiles with a few exemptions such as shinglebacks, the red back salamander and the Caribbean cleaner goby. In contrast, up to 90 % of all bird species display some degree of monogamy and species from several genera of birds including geese, swans, and eagles form

lifelong pair bonds. A large phylogenetic study comprising 2,545 mammalian species showed that 9 % of mammals are socially monogamous, a number previously thought to be slightly lower (3–5 %) (Lukas and Clutton-Brock 2013).

Evolutionary Explanations of Pair Bonding

The large disparity in monogamy occurrence between different classes of animals has been explained by factors related to parental investment. In mammals, for example, following birth, offspring get their nutriment exclusively from the lactating mother and therefore only in rare cases do female mammals rely on paternal investment. In birds however, both parents can contribute equally to feeding the offspring and the evolutionary benefit of bi-parental care, and consequently pair bonding, is more prominent and therefore common.

Ultimate explanations for mammalian monogamy have been a topic for debate in evolutionary biology. There are two prevailing explanations for its existence. One suggests social monogamy evolved because of the fitness benefits this mating strategy gives offspring and to some extent mothers, such as male resource provisioning and protection against predation and aggression from competing males, including infanticide. The alternative hypothesis proposes that monogamy may represent a mate guarding strategy and could have evolved in situations where males were unable to defend access to more than one female. Based on phylogenetic evidence, the evolution of social monogamy in mammals does not appear to have been driven by high risk of male infanticide and paternal care seems to be a consequence rather than a cause of social monogamy (Lukas and Clutton-Brock 2013). Instead, monogamy in this class seems to have evolved where females are intolerant of each other and the population density is low, and thus represents a male mating tactic that has developed where males are not able to defend access to multiple females. Spatial properties of the social environment males live in, as

well as how individuals can navigate this environment, have therefore played an important role in the evolution of pair-bonding in mammals.

Proximate Causes of Pair Bonding

Regarding neural mechanisms of pair-bonding behavior, most of our knowledge today comes from studies in a particular group of rodents, voles. In the socially monogamous prairie vole (*Microtus ochrogaster*), males and females form long-lasting pair-bonds and both sexes take care of offspring. Research using this rodent as a model organism has provided remarkable insights into the neurobiology of social attachments and diversity in social behavior. In both male and female prairie voles, mating facilitates the development of an enduring pair bond, which can be assessed in the laboratory using a partner preference test (Johnson and Young 2015). Bonded animals prefer to spend time in close contact with their partner compared to a novel stimulus animal. Pair-bonding behavior in prairie voles is regulated by multiple neural mechanisms involving several brain regions and is speculated to be the result of linking the neural encoding of the social stimuli of the partner with the reward system, increasing the reinforcing value of partner stimuli relative to other social stimuli. Of these neural systems, neuropeptide dependent circuitry is particularly well studied and important for pair bonding. The peptides arginine vasopressin (AVP) and oxytocin (OT) have been shown to play important roles in the neurobiology of social behavior in animals (Johnson and Young 2015). Both are neuropeptides and are mainly synthesized by neurons of the paraventricular nucleus of the hypothalamus. They structurally differ only by two amino acids and share the same evolutionary origin. OT is implicated in a wide range of social behaviors including parental care, social motivation, and cognition (Ross and Young 2009). AVP regulates several male-typical behaviors, including territorial behavior, intrasexual aggression, and paternal care (Young and Wang 2004). Both OT and AVP are important for the formation and

expression of social memory including mate recognition, and these peptides have central roles in the regulation of pair-bonding behavior in prairie voles. Dopamine, which is involved in reinforcement learning in nonsocial context, and the opiate system also play important roles in the formation and maintenance of the pair bond.

Vasopressin and Pair Bonding in Voles

In laboratory experiments, pair-bonding behavior in male prairie voles has been shown to be facilitated by brain AVP and prevented by central injections of a vasopressin 1a receptor (V1aR) antagonist (Young and Wang 2004). The neuro-anatomical distribution of V1aR differs considerably between vole species. For example, prairie voles display relatively high density of V1aR in the ventral pallidum, a component of the mesolimbic dopamine system, compared to the non-monogamous meadow vole (*Microtus pennsylvanicus*). Remarkably, increasing the density of V1aR in ventral pallidum of meadow voles, using viral vector mediated gene transfer, makes these voles more social and display prairie vole like pair-bonding behavior (Young and Wang 2004). These findings suggest that AVP, acting on V1aR, played an essential role in the evolution of monogamy in voles.

Studies in voles have also provided intriguing insights into the genetic regulation of pair-bonding behavior. While the coding region of the gene coding for V1aR (*avpr1a*) is 99 % homologous between prairie and meadow voles, there is an approximately 400 base pair long repeat sequence (microsatellite) in the prairie vole promotor region not found in meadow voles. This particular part of the gene has in laboratory experiments been shown to associate with levels of V1aR binding in some brain areas in prairie voles as well as both intra- and interspecies variation in pair-bonding behavior (Young and Wang 2004).

In addition to laboratory experiments, the influence of variation in the vasopressin 1a receptor gene on pair-bonding behavior has been studied in more ecologically relevant settings (Phelps 2010). In the wild, male prairie voles can display

two distinct mating tactics. The “resident” strategy involves males pairing with a female and staying within constricted home-ranges allowing them to effectively guard their mate and protect offspring. In contrast, “wanderers” display a more opportunistic strategy. These unpaired males have large home-ranges overlapping several conspecifics’ territories and will mate with unpaired females as well as with paired females willing to engage in extra-pair copulations. Variable lengths of the *avpr1a* promoter microsatellite predict V1aR density in the retrosplenial cortex, a brain region important for spatial memory, and in the wild abundance of V1aR is associated with space use, sexual monogamy, and mate guarding ability. In particular, “wanderers” with relatively low levels of V1aR in the brain had higher reproductive fitness than those with high densities of this receptor, possibly driven by spatial ability.

In addition to microsatellite variation, single nucleotide polymorphisms (SNPs) in the prairie vole *avpr1a* have been shown to strongly predict V1aR density in the retrosplenial cortex and associate with sexual fidelity in male prairie voles (Okhovat et al. 2015). Interestingly, the variation in this gene important for both receptor density and behavior seems to be maintained through balancing selection. Prairie voles exhibit wide fluctuations in population density and future studies will investigate if density dependent selection promote variation in *avpr1a* and related behaviors. Taken together, these findings indicate that brain systems involving AVP play an important role in the evolution of pair-bonding behavior and are in line with the phylogenetic data suggesting that spatial navigation contributed to the evolution of social monogamy in mammals.

Oxytocin and Pair Bonding in Voles

The neuropeptide oxytocin plays a similar role as vasopressin in regulating pair-bonding behavior in the prairie voles. While previous work has suggested that the effects of vasopressin and oxytocin are highly sexually dimorphic, it is becoming increasingly clear that this picture is an oversimplification. In particular, recent research has shown the OT system to be important for

both male and female pair-bonding behavior (Johnson et al. 2016). Central OT infusion facilitates partner preference formation, and central infusion of an OT receptor antagonist (OTA) prevents mating-induced partner preference, in both males and females. Oxytocin acts within the mesolimbic dopamine reward pathway, including the nucleus accumbens and prefrontal cortex, to facilitate partner preferences in prairie voles, although a contribution of other brain regions cannot be excluded. The prefrontal cortex and nucleus accumbens of the prairie vole have high densities of OT receptors, and site-specific infusion of an OTA in either region prevents mating-induced partner preference formation in female prairie voles. Interestingly, nonmonogamous vole species, such as meadow voles, do not express OT receptors in the nucleus accumbens.

The density of OT receptors in the nucleus accumbens is under strong genetic control in prairie voles demonstrated by work showing that SNPs in the oxytocin receptor gene explain more than 70 % of the individual variance in oxytocin receptor levels (King et al. 2015). This finding supports the evolutionarily pertinent possibility that relatively small changes in the genetic code can have a large impact on the brain phenotypes and could help explain both the neuroanatomical and behavioral differences between closely related vole species.

Less is known about the influence of the OT system on pair-bonding behavior in the wild, but studies have shown that the levels of OT receptors in the nucleus accumbens is higher in the more monogamous resident male prairie voles compared to wanderers. Future evolutionarily informed studies will investigate the relationship between variation in the OT receptor gene, brain phenotypes, behavior, and reproductive success in prairie voles.

While prairie voles have been most intensively studied with regard to neural mechanisms, there is evidence that the OT/AVP system also plays a role in pair-bonding behavior in primates (French et al. 2016) and song birds (Klatt and Goodson 2013).

Conclusion

The occurrence of pair-bonding behavior varies to a large extent between different groups of the animal kingdom, and these differences can be explained evolutionarily by factors related to parental investment. Among mammals it seems pair-bonding has primarily evolved as a male mating tactic developed in situations where mate guarding of multiple females has been associated with low fitness. Studies in voles have shown pair-bonding behavior to be regulated by neural systems involving the neuropeptides oxytocin and vasopressin.

Executive Functioning

Elaine Arrington, Connor Patros and R. Matt Alderson
Oklahoma State University, Stillwater, OK, USA

Synonyms

Cognitive control; Executive control

Definition

Executive functions (EFs) refer to a broad class of complex cognitive processes that guide the allocation and use of lower-order cognitive processes and behaviors (e.g., motor responses,

perception (Snyder et al. 2015)). Examples of EFs include planning and organizing thoughts and behavior, maintaining and manipulating information in short-term memory, inhibiting undesired responses, maintaining focus on a selected task, and flexibility in the application of sets of mental rules in accordance with environmental contingencies.

Introduction

Differences in individual EF abilities are linked to a host of important outcomes, including academic achievement, interpersonal effectiveness, occupational functioning, and general mental health (Snyder et al. 2015). There is considerable variability in EF measurement and the specific constructs that are subsumed under the umbrella EF term. Indeed, there is no general consensus on the best conceptualization of EF (Snyder et al. 2015), which has led to the examination of various neurocognitive processes as possible EFs. For example, findings from Miyake et al. (2000) provide evidence for a three-factor model of EF in young adults, with factors reified as shifting, updating, and inhibition. These factors represent separable, albeit highly correlated, neurocognitive processes. In contrast, findings from developmental literature suggest that EF may be best represented by a more unitary, domain-general structure, particularly at the preschool age (Wiebe et al. 2011). Working memory, planning, set-shifting, inhibitory control, and self-monitoring reflect the most commonly examined EFs and are detailed below.

Organizational EFs

Working Memory

Working memory (WM) is a limited capacity neurocognitive system responsible for the temporary storage and mental manipulation of phonological and visuospatial information. Several theoretical models present opposing hypotheses regarding the structure of the WM system. For example, Baddeley's (2000) multicomponent model of WM proposes two independent phonological

and visuospatial storage/rehearsal slave systems, a domain general central executive, and an episodic buffer responsible for the storage of bound, multimodal stimuli. Alternatively, Cowan (1999) proposes the embedded processes model, suggesting that WM is defined as a limited capacity focus of attention on information activated from long-term memory. Overall, equivocal findings from experimental and factor analytic studies provide support for various theoretical models of WM, which leads to conflicting hypotheses regarding the true definition and/or structure of WM.

There also exists an abundance of heterogeneity across methodological approaches used to measure WM. For example, standardized intelligence tests classify tasks that place high demands on short-term storage/rehearsal processes (e.g., digit span forward and backward) as WM tasks, while numerous experimental studies utilize tasks that explicitly require mental manipulation and/or updating of information. Nevertheless, given the well-established relationship between WM and other vital cognitive processes (e.g., attention), the reliance of numerous complex cognitive activities for adequate WM functioning, and the positive relationship between strong WM and positive life outcomes, the WM system is likely the single most influential EF within the realm of human cognition.

Planning

Planning is the process of deliberating possible options, steps, and/or outcomes necessary to successfully attain a goal. Effective planning requires the use of several upstream cognitive processes that allow an individual to compare and contrast choice-options, reflect on outcomes of previous decisions, and use forethought to determine the consequences of carrying out particular actions. Consequently, it is difficult to examine planning as a discrete EF, given many planning tasks indirectly place demands on additional neurocognitive processes (e.g., WM). Nonetheless, paradigms such as the Tower of London, Tower of Hanoi, and Porteus Maze tasks are commonly used to measure planning. Metrics from these tasks most often include the

amount of time spent deliberating, number of errors made, and frequency of successful task completion.

Set-Shifting

Set-shifting, sometimes referred to as *task-shifting* or *cognitive flexibility*, is an EF that allows for the disengagement of attention toward a prepotent response or problem solving strategy, and subsequent reengagement in a novel response or strategy. This EF is critical with regard to one's ability to efficiently adapt to novel situations, think flexibly, and alter behavioral or cognitive perseverative response styles. Set-shifting is often referred to as a "higher order" EF, given its reliance on the adequate functioning of more basic cognitive processes (e.g., attention, WM). The Wisconsin Card Sorting Task and Change Task are commonly used to examine set-shifting abilities, as both tasks intermittently require individuals to alter prepotent response strategies for successful completion.

Regulatory EFs

Inhibitory Control

Inhibitory control is a broad term that is applied to both cognitive and behavioral processes. *Behavioral inhibition* refers to the discontinuation and/or withholding of prepotent responses and is frequently measured using tasks such as the Go/No-go and Stop Signal paradigms. These tasks require examinees to withhold responding to prepotent stimuli when stop-stimuli are presented. *Cognitive inhibition*, in contrast, refers to the filtering of task-irrelevant information from entering the WM system, in turn allowing for improved accuracy and/or efficiency of cognitive processing. This interference control results in more efficient processing of relevant information and consequently greater likelihood of successful encoding and/or retrieval. The Stroop task is the prototypical task utilized to examine cognitive inhibition.

Self-Monitoring

Self-monitoring refers to the internal regulation of actions responsible for gauging the quality,

accuracy, and acceptability of a particular cognition or behavior. While self-monitoring appears to rely on other EFs, such as inhibitory control and WM, the evaluative component of this EF differentiates it from other processes. That is, self-monitoring allows for live introspection and provides salient information regarding one's trajectory toward accomplishing a particular goal. Self-monitoring is challenging to objectively measure given the inherent difficulty associated with examining internalized self-talk; however, tasks that allow for the examination of perseveration and/or self-correction of errors (e.g., Tower of Hanoi task) provide estimates of an individual's ability to monitor their behavior.

EF and Neural Correlates

Findings from neuroscience studies demonstrate that frontal and parietal structures (e.g., dorsolateral prefrontal cortex, anterior cingulate cortex) are more active during the completion of EF tasks, relative to non-EF tasks (Niendam et al. 2012). Localizing these complex cognitive processes to singular neural regions or structures is overly simplistic. Consequently, most contemporary research indicates that EF performance is dependent on a complex interaction between larger neural networks that span across frontal and parietal lobes, rather than discrete neural structures.

EF and Psychopathology

Deficits of EF are associated with a number of mental health disorders including schizophrenia, internalizing disorders, and externalizing disorders. For example, large-magnitude deficits of shifting, inhibition, updating, and WM have been revealed in studies of schizophrenia. Deficits in those same EFs are also associated with depression, although the magnitude of deficits is smaller (small to medium effect sizes), while medium sized deficits in shifting, inhibition, and WM are associated with bipolar disorders (Snyder et al. 2015). EF has received relatively less attention in anxiety research, with the notable exception

being studies of threat-related attentional biases. Specifically, meta-analytic research has indicated a consistent attentional bias in which anxious individuals are more likely to attend to threat-related information (Bar-Haim et al. 2007).

EF problems are strongly related to externalizing disorders, such as attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), and conduct disorder (CD), and recent models suggest ADHD-related executive dysfunction is the core feature of the disorder (Alderson et al. 2010). That is, moderate- to large-magnitude deficits in WM, inhibition, and set-shifting are consistently found in children and adults with ADHD (Willcutt et al. 2005). While findings from studies of ODD and CD have been relatively mixed with respect to WM functioning, findings of inhibitory deficits have been relatively consistent.

EF Training

EF training has been hypothesized as a fruitful intervention for remediating EF deficits associated with mental health and general cognitive functioning. These brain training programs involve cognitive exercises, usually completed via computer, that are purported to improve EF strength, in a process akin to increasing muscle strength by lifting weights. Multiple EFs, such as inhibition, WM, and emotion regulation, have served as targets of these interventions (Rapport et al. 2013).

While early findings appeared promising, recent meta-analytic research indicates that these EF training interventions have limited utility in terms of the long-term gains and transfer effects (Rapport et al. 2013). Specifically, although studies of EF training have demonstrated increased performance on tasks that are similar to the task on which the individual was trained, there has been less support for performance gains on tasks dissimilar to the trained task (e.g., academic achievement).

Conclusion

EFs are a broad class of cognitive abilities that play a fundamental role in navigating one's

environment by maintaining relevant information in mind, suppressing undesired or inappropriate responses, and following-through with tasks. They also help individuals organize their thoughts, plan behavior, and change their course of action as needed based on environmental demands. There is no consensus on what exactly constitutes EF, but WM, inhibition, updating, and shifting are among the most-often studied EFs. Moreover, while EFs are frequently thought of as “frontal lobe functions,” neuroimaging/functioning studies have indicated that EFs rely upon a diffuse neural network. Nevertheless, given the indispensable role of EFs in everyday life, it is not surprising that deficits in these neurocognitive processes are incorporated into etiological models of several mental health disorders.

Activity that requires physical effort, frequently associated to the maintenance or improvement of health and fitness

Introduction

Demanding physically activities have always been part of hominid life. In a hunter-gatherer context, frequent physical activity was required for survival (Lieberman 2015b). The ability to run long distances escaping from predators or hunting preys, caring food or occasionally babies, for example, could be considered a crucial form of physical activity for humans. Hence, adaptations such as bipedalism and efficient heat exchange mechanisms were essential for human evolution.

Adaptations to Exercise: Heat Exchange and Bipedalism

Physical activity generates heat, and excessive heat may represent a risk to the organism's health and survival. Adaptations that enable efficient heat release and exchange, such as sweating, nasal and brain cooling, and bipedal posture, were essential to human survival (Lieberman 2015a).

The ability of cooling the body through evaporative heat loss is a very efficient form of fast heat exchange, especially in warm environments. Although it is metabolically costly, the secretion of vaporized water through the skin is the main responsible for most of the heat exchange in humans. Another mechanism of heat exchange is through the respiratory system, fresh inhaled air cools the internal organs, and the heat is released in the warm exhaled air. Anatomical adaptations of humans (e.g., high density of eccrine glands in the scalp) also facilitate the cooling of essential body parts, such as the brain.

Finally, an important adaptation in human evolutionary history is our atypical way of locomotion: bipedalism. Despite the costs of loss of speed and stability compared to alternative ways of locomotion (e.g., knuckle-walking), bipedalism provided strong fitness benefits, such as a more efficient long distance locomotion, food acquisition, ability to observe possible predators, and reduction of the body area exposed to solar radiation (Lieberman 2015b). In addition, bipedalism is energetically more efficient than alternative

forms of locomotion, such as knuckle-walking (Lieberman 2015a).

Besides their direct effect on survival, these adaptations (e.g., heat exchange and bipedalism) have allowed humans to endure frequent and intense physical activities. For example, the ability to exercise influenced many aspects of human life, including mate choice and disease prevention.

Physical Appearance and Mating

Physical traits related to attractiveness that can be modified through exercise, such as strength, athletic prowess, and a heavily muscled body, are often correlated with health and may be used as indicators of good genes (Zahavi 1975; Nedelec and Beaver 2014; Lu et al. 2015; Buss 2015; Buss and Schmitt 2016). Because physical features related to an increased immunocompetency are perceived as attractive (Buss 2015), highly attractive partners (vs. unattractive partners) are likely to generate healthier offspring, more likely to survive. Thus, they would have a selective advantage over less attractive/healthy individuals. Because developing and maintaining attractive physical attributes is costly – for example, a skin is more likely to develop scars in environments with high parasite load (Buss 2015) – highly attractive physical attributes can be honest signals of the survival capacity of an individual (Zahavi 1975). Consequently, the body shape, weight, and muscle structure of an individual who is unable to endure intense exercise (e.g., due to unhealthy joints) would be very different from that of a healthy individual, who is able to work out. Hence, healthy individuals with the ability to engage in physical activity would be more easily identified as attractive, better mates, good providers, and a good stock of genes (Lu et al. 2015; Buss 2015; Nedelec and Beaver 2014).

Exercise in Modern Society

Modern environmental conditions allow humans to be constantly physically inactive. The combination of a sedentary routine and a high-caloric

diet lead to an increase in the prevalence of metabolic diseases that were relatively infrequent in the past (e.g., cardiovascular diseases). Although the ability to exercise was not directly selected for its therapeutic benefits, exercising became an alternative to avoid illness such as obesity, diabetes, coronary diseases, and comorbidities (Lieberman 2015b; Penedo and Dahn 2005).

Conclusion

In sum, due the environmental conditions that humans were submitted in their evolutionary history, physical activity was a constant in the hunter-gatherer routine. Such dynamic lifestyle may have selected for some unique adaptations like bipedalism and efficient mechanisms of heat exchange.

Physical activity was a constant necessity in early human life, and exercise was not a choice but a necessity for survival. Nevertheless, the selective pressures humans had to face were fundamental to modulate what is known as exercise in modern society, from home workouts to Olympic training.

Exotic-Becomes-Erotic Hypothesis

Daryl Bem
Cornell University, Ithaca, NY, USA

Synonyms

[Erotic orientation](#); [Sexual orientation](#)

Definition

An individual's predominant sexual orientation toward men and/or women.

Introduction

There is evidence that biological factors, including genes, are correlated with an individual's sexual orientation. (For a recent review, see Bailey et al. 2016). The Exotic-Becomes-Erotic (EBE) hypothesis proposes that biological factors do not, however, directly influence an individual's sexual

orientation but act indirectly by influencing the child's preferences for sex-typical or sex-atypical activities. Children who prefer sex-typical activities and who play primarily with same-sex playmates are called *gender conforming*; children who prefer sex-atypical activities and who play primarily with opposite-sex playmates are called *gender nonconforming*. These preferences lead children to feel different from either opposite- or same-sex peers – to perceive them as dissimilar or exotic: Gender-conforming children will experience opposite-sex children as different from themselves and gender-nonconforming children will experience same-sex children as different from themselves. This feeling of difference produces heightened emotional arousal to members of the dissimilar sex that subsequently becomes transformed into an erotic attraction to them (Bem 1996).

Evidence that Genes Are Correlated with Sexual Orientation

To determine whether a physical feature or personality trait is correlated with genetic factors, researchers look to see whether individuals are more similar to close relatives on that trait than they are to more distant relatives. For example, individuals' heights are more closely related to the heights of their parents than to the heights of their aunts and uncles. This implies that the physical trait of height has a significant genetic component or is *heritable*. Because they control for age, sex, and the home environment, the best studies are those that compare identical twin pairs (called *monozygotic* twins) with a matched sample of same-sex fraternal twin pairs (*dizygotic* twins). Monozygotic twin pairs share all of their heritable genes with one another whereas dizygotic twin pairs share only about half of their heritable genes with one another. So if monozygotic twin pairs are more alike on a trait than are same-sex dizygotic twin pairs, we can infer that the trait is partially heritable.

Studies have now established the heritability of sexual orientation for both men and women.

In a study of gay men who had twin brothers, 52 % of monozygotic twin brothers were also gay compared with only 22 % of dizygotic twin brothers. Some men also had adopted brothers in their families, men who did not share any heritable genes with their gay brothers: Only 11 % of those adopted brothers were also gay (Bailey and Pillard 1991). A parallel study of lesbians showed the same pattern: 48 % of monozygotic twin sisters were also lesbian compared with only 16 % of dizygotic twin sisters and 6 % of the lesbians' adopted sisters (Bailey et al. 1993). A subsequent study of nearly 5,000 twins who had been drawn from a twin registry confirmed the heritability of sexual orientation for men (Bailey et al. 2000).

Gender Conformity/Nonconformity Is Also Correlated with Sexual Orientation

There have now been many retrospective and prospective studies that confirm a correlation between childhood gender conformity/nonconformity and an adult sexual orientation (Bailey and Zucker 1995). The largest of these compared nearly 1,000 gay men and lesbians with 500 heterosexual men and women on many aspects of their childhoods, including family relationships and early sexual experiences with both sexes. None of these correlated with their later sexual orientations. In fact, there was only one childhood variable that correlated with adult sexual orientation for both men and women: gender conformity/nonconformity (Bell et al. 1981).

For example, many more gay men than heterosexual men reported that as children, they had not enjoyed typical boy activities (such as sports), had enjoyed typical girl activities, and had had more childhood friends who were girls. Similarly, more lesbians than heterosexual women reported they had not enjoyed typical girl activities, had enjoyed typical boy activities (especially sports), and had had more childhood friends who were boys.

Gender Conformity/Nonconformity and Feeling Different

The Exotic-Becomes-Erotic hypothesis (EBE) proposes that gender-conforming children will feel different from opposite-sex children, and gender-nonconforming children will feel different from same-sex children. The large study, cited above, found that 71 % of the gay men and 70 % of the lesbians in the sample had felt different from their same-sex peers during childhood. When asked in what ways they had felt different, they overwhelmingly cited gender-related reasons. Gay men were most likely to reply that they had not liked sports; lesbians were most likely to reply that they had liked sports more and had been more masculine than other girls. In contrast, fewer than 8 % of heterosexual men and women said that they had felt different from same-sex childhood peers. Those who did tended to cite nongender-related reasons such as having been poorer, more intelligent, or more introverted than other children.

How Does Exotic Become Erotic?

In his first-century Roman handbook, *The Art of Love*, Ovid advised any man who was interested in sexual seduction to take the woman in whom he was interested to a gladiatorial tournament because she would there be more easily aroused to passion. A contemporary version of Ovid's claim can be understood to be a special case of what psychologists call the two-factor theory of emotion. It states that the physiological arousal of our nervous system can provide cues that we feel emotional but that the more subtle judgment of *which* emotion we are feeling often depends on our interpretation of the surrounding circumstances. The experience of erotic arousal thus arises from the conjunction of physiological arousal and circumstances that permit it to be interpreted as erotic arousal.

There is now experimental evidence that an individual who has been emotionally aroused – whether that arousal is neutral, pleasant, or

unpleasant – will show heightened sexual responsiveness to an appropriate target person. In one study, male participants were physiologically aroused by running in place, by hearing an audio-tape of a comedy routine, or by hearing an audio-tape of a grisly killing. No matter how they had been aroused, these men reported greater erotic interest in a physically attractive woman than did a control group of men who had not been aroused (White et al. 1981).

This effect has also been observed physiologically. Men and women were shown an erotic video while their physiological sexual arousal was monitored (penile erection in men and vaginal blood flow in women). But before seeing the erotic video, half the participants first saw a disturbing video of a grisly automobile accident; the remaining participants saw a video of peaceful landscapes. Participants who had seen the disturbing video subsequently showed more sexual arousal to the erotic video than did those who had seen the peaceful video (White et al. 1981).

The Exotic-Becomes-Erotic hypothesis thus proposes that an individual's experience of feeling different from same- or opposite-sex peers in childhood produces a physiological arousal that gets eroticized when the maturational, cognitive, and situational factors coalesce to provide the defining moment when it can be interpreted as sexual arousal. The timing of this moment, however, is influenced by several factors, including actual sexual experience with opposite- and same-sex peers and the norms of the surrounding culture. The heightened visibility of gay men and lesbians in our society in recent years is leading individuals who experience same-sex arousal to recognize it, label it, and act on it at earlier ages than previously.

An Empirical Test of the Exotic-Becomes-Erotic Hypothesis

The discovery that genes are correlated with sexual orientation has led some people to believe that there must be a “gay” gene or set of genes that directly influence sexual orientation. In contrast,

the Exotic-Becomes-Erotic hypothesis proposes that the link between genes and sexual orientation is only indirect: The genes influence early personality traits that socially define a child as gender-conforming or gender-nonconforming, and it is that gender conformity or nonconformity that provides the important intervening link between the genes and sexual orientation. Because the large study of twins, cited above, assessed both sexual orientation and gender conformity/nonconformity, those data enable a test for both the direct and the indirect paths from genes to sexual orientation (Bem 2000).

First, the data confirmed the first link proposed by the Exotic-Becomes-Erotic hypothesis: Monozygotic twins were significantly more alike on gender conformity/nonconformity than were same-sex dizygotic twins. This was equally true for both men and women. Second, the data confirmed the second link proposed by the hypothesis: Childhood gender conformity/nonconformity was significantly correlated with sexual orientation. When the direct and Exotic-Becomes-Erotic paths were statistically compared, it was found that the indirect path accounted significantly for the correlation between genes and sexual orientation but the direct path did not (Bem 2000).

This one test of the Exotic-Becomes-Erotic hypothesis does not, of course, establish the validity of the entire theory, which proposes several other links and processes (e.g., the link between feeling different in childhood and later erotic attractions). But it does demonstrate that the correlation between the genes and sexual orientation should not be interpreted as a direct causal link.

Conclusion

It is now considered a truism that most human traits and behaviors are influenced by both biological and environmental/developmental variables and their interactions. But because sexual attraction and behavior appear to be so obviously grounded in our evolutionary history, people have been quick to assume that there must be a “sexual-orientation” gene. But there is also a correlation

between genes and getting divorced: If a monozygotic twin is divorced, his or her twin is also more likely to be divorced than if they are dizygotic twins (McGue and Lykken 1992). And yet nobody has proposed that there must be a “divorce” gene. This is because it is obvious that there must be intervening heritable personality traits (e.g., irritability, clinical depression) that account for the link between genes and divorce. The Exotic-Becomes-Erotic hypothesis is an example of this same reasoning applied to sexual orientation.

Expanding Circle, The

Shubham Gupta

Integral College of Nursing, Lucknow, India

Introduction

As it is the basic concept which is taught at school level to everyone that, “Man is a social animal.” Without socialization one cannot develop his personality. Many other important phases of life cannot be achieved without socialization. A mother initiates this process from very early stage of childhood and teaches their child to explore himself and to maintain contact to the person who cuddles him/her, loves him/her, care him/her, and concern about the child. These things continue in more compact form when child enters as a student and institutionalization occurs. His/her teachers teach him moral values along with academic curriculum like sharing of tiffin with other classmates, friends, and many more such activities. Basically all these activities just expand the circle of socialization of the child and helps in the development of personality too.

The idea of the “expanding circle” was first penned by the Irish historian WEH Lackey in his 1869 book, “A History of European Morals.” Lackey wrote that we expand the number of people who deserve our moral consideration like a circle. At one time, he explained, “philanthropic affection only embraces the family, soon in the expansion of the circle first a class, then a nation, then a coalition of nations, then all humanity, and finally, feel its effects is done.” (Warner 2014).

Definitions

The relationship between reason and ethics is truly defined as “*The Expanding Circle*.”¹ Relationship between morality and biological capacity of altruism is explained by Singer. As per him, altruism is well defined for wider circles and then it is considered as moral and limited to family, community, tribe, or a country.

This is due to human capacity, which “normalizes or universalizes” our philanthropic tendencies beyond the groups we are biologically reflected upon. As such, reason is not contrary to feelings and instincts but is formed on the basis of it (Browning 1982). The expansion cycle is therefore a product of both ethics and sociology. The process by which a human-being begin at infancy acquires the habits, beliefs, and accumulated knowledge of society through education and training for adult status is the expanding circle.

Peter Singer’s critique of sociology as applied to ethics comes from the It’s-OK-But-It-Presumes- school of thought. Rather than dismiss Wilson’s perceptions of altruism, Singer spent much time restoring and defending notions of kin selection, interpersonal altruism, and, to a lesser extent, the genetic basis for group selection. With homage to Dawkins, we hear again about the strategies of the prisoner’s dilemma and other situations in which mutual altruism is superior to pure selfishness. Only in the second half does Singer offer his particular view, which is that moral behavior reflects the human capacity for reasoning. As individuals and cultures mature, the reason allows the expansion of the moral code, sometimes to a growing population.

We should start designing our culture so that it encourages widespread concerns without the disappointment of important and relatively permanent human desires. Certainly not the last word of ethics in sociology but in a way unrelated and similarly inadequate as the Singer Defense of Reason (Kirkus 1980).

Moral extension and moral concern and refers to the breadth of entities considered worthy of treatment. A morally less expensive person restricts concern for entities that are considered “close” (e.g., their family). A more moral extender extends moral care and consideration beyond these boundaries to “distant” institutions (e.g., animals or plants). Therefore, moral elaboration captures the desire to increase moral concern for others (the “breadth” of an individual’s moral world). Moral foundation theory (MFT; Haidt and Joseph 2004) focuses on the basic foundations that people rely on to make ethical decisions, such as the notion of care/loss or sanctity/

degradation, rather than moral consideration that is an appropriate entity. Moral elaboration also differs from moral identity; self-conception is organized around the degree to which a set of desirable moral traits (e.g., caring, compassionate, honest) is individually valued (Aquino and Reed 2002; Crimston et al. 2016; Caplan 1983; Patience 1984).

Meaning

The process of expanding the circle begins during childhood by which individuals acquire the values, habits, and attitudes of a society. Exposure of a young domestic animal (such as a kitten or puppy) to a variety of people, animals, and situations to minimize fear and aggression and promote friendliness also expands the circle. Some adult dogs, because of a lack of socialization combined with genetic tendencies, can never transfer certain individuals from the “unfamiliar” to the “familiar” category (Steven 2011).

Theories Related to Expanding Circle

Sigmund Freud’s Psychoanalytic Theory

According to Freud, human behavior, experience, and cognition in childhood are largely determined by unconscious drives and events. First, human behavior, experience, and cognition are largely determined by irrational drive. Those drives are largely unconscious. Attempts to bring those drives to awareness, as a defense mechanism, meet psychological resistance. Apart from the inherited constitution of personality, one’s development is determined by events occurring in childhood. Conflict between a conscious approach to reality and unconscious (repressed) content can result in mental disturbances, such as neurosis, neurotic symptoms, anxiety, depression, etc. Freedom from the effects of subliminal material is achieved through bringing this material into consciousness.

Jean Piaget’s Cognitive Development Theory

While studying the field of education, Piaget identified two processes: accommodation and

assimilation. Assimilation describes how humans experience and adapt to new information. It is the process of taking an environment and new information and fitting it into an already existing cognitive schema. Housing, unlike assimilation, is the process of taking one’s environment and new information and changing an already existing schema to fit new information.

Daniel J. Levinson’s Theory of Positive Adult Development

As a theory, positive adult development claims that development continues after adolescence, long into adulthood. In positive adult development research, scientists question not only whether development stops after adolescence but also the notion that it is popular by many gerontologists that it declines after late adolescence. Positive adult developmental processes are divided into at least six areas of study: hierarchical complexity, knowledge, experience, expertise, knowledge, and spirituality.

Implications to Expand the Social Circle

Connect With Connectors

A great way to expand your social circle is to connect with someone through whom you will meet many other people. Those “connectors” are the type of people who have friends on Facebook by the thousands, host parties, and always hook up with a large group of people. Often, these are very open people and are easier to connect with than you think. They may not have time to invest in a deep friendship with you, but they like to know more interesting people to add to their circle (Warner 2014).

Meet New People Constantly

A great habit is always meeting people whom you can add to your circles. In reality, all the people you meet will not become your friends and all your current friends will not last forever. This is why I always say that if you are not making new friends, then you are actually making less. I suggest that you go to places where it is easy and appropriate for someone to walk and

introduce you. Ideally, you need to visit places where others are open to meeting new people as well. Common places to meet with new people might be trade shows, opening nights, galas, cultural or charitable events, seminars, and talks (Dunstan 1984).

Establish Yourself as a Giver of Value

When meeting a lot of people, you have to “hook.” Nothing hooks better than having a donor attitude. First, imagine what they say and imagine if you were theirs; see the world through their eyes. Second, be prepared to share stories, contacts, or quick advice to those who are talking to them.

When you meet new people, there are some psychological theories that determine whether they want to meet you again. It works on a subliminal level. One of the most important principles is the giver/taker attitude. If they think you only care about yourself, the connection is not going to happen.

You can illustrate the giver’s attitude in two ways. The first is really about hearing about what they say, imagining the world through their eyes, and giving them their opinions on their stories and situations. The other way is to prove that you are ready to share the same type of stories they are talking about or introduce them to someone who can help them (Denman 1983).

Commit to a Local Community

One of the fastest ways to promote your social life is to join a community that has the type of people you want as a friend. This community should be in your local area and social gathering once a month, or longer.

You get what you do, which you probably find on Meetup.com, and help those who run it. They most likely accept it, even if they don’t need that help; they will only be what you are interested in. It works great because it gets you from everyone, and because it establishes you as a giver of value (Dent 1984).

Reach Out to People on a Regular Basis

If you want to keep your social circle alive, it is important to stay in touch. You need to follow-up

with people you just met and catch up with existing friends. The challenge here is that we get distracted and forget about it, and later regret it.

To solve this problem, you can create a weekly ritual, where you spend only one hour calling, texting, and messaging people. Just put a specific day and time on your calendar, and do it every week. A great time to do this is Tuesday or Wednesday, as it gives you the opportunity to plan for the weekend with people (Clark 1985).

Know the Kind of Friends You Want in Advance

Do a little planning before you start spending more time on making friends. Try to know what kind of people you want to hang out with. List some qualities, character traits, or interests, and don’t hesitate to be a little more ambitious than usual. This is important because it allows your mind to quickly tell if the person you meet can be a great fit for you.

Here are some qualities you can start: giver, interesting, fun, ambitious, honest, loyal, curious, and reliable. If you want, you can add others, and you can also make a list of activities you want to do with your future friends. These lists will not be definite, but the clarity they bring will save you a lot of time and frustration. I also recommend that you take a little time to learn about friendship and how it works.

Expanding circle can provide many benefits to your physical and mental health. Longevity, better physical and mental health, and reduced risk of other organic mental disorders are also benefits of expanded circle.

Conclusion

Socialization is important because it helps to maintain societies and cultures; it is also an important part of personal development. We are influenced by both nature (our genetic and hormonal makeup) and nutrition (the social environment in which we are raised). Sociology is most concerned with how the way society influences

our behavior patterns makes it clear that behavior varies across class and gender.

Our direct interactions with social groups, like families and peers, teach us how others expect us to behave. Similarly, formal and informal institutions of a society socialize their population. Schools, workplaces, and media communicate and reinforce cultural norms and values. Socialization is a lifelong process, as we enter new stages of life, such as adulthood or senior age. Resocialization is a process that removes the socialization that has developed over time and replaces it with newly learned rules and roles. Because it incorporates old habits that have been created, resocialization can be a stressful and difficult process. So expanding circle incorporates personal development, personality development, and also the development of different phases of life. This allows for the maximum of effective.

In fact, the socialization gives us the tools to fill our evolutionary roles. They are our building blocks.

Misuse/misapplication of psychological mechanisms

Definition

The process by which our psychological mechanisms are exploited by evolutionary mismatch, or the effect by which our rate of technological advancements far outweighs the speed of evolution, leading to a “mismatch effect.”

Introduction

As discussed in the previous chapter, evolutionary mismatch is a phenomenon by which our minds are still essentially Stone Age minds meant for hunter-gatherer lives. The rate of technological advancement has been far too fast for our bodies to catch up, leading to various situations by which we are “mismatched” with our bodies to our current environment. Many businesses have taken advantage of this mismatch effect and sell their product through the knowledge of what will appeal to consumers based on what we psychologically desire.

Food and Other Products

Food is a classic example of something that is taken advantage of to appeal to consumers.

Turning on any TV station will inevitably result in watching commercials that appeal to a certain demographic. Often times, food is depicted on these commercials, and made to look extremely appealing to the eye, and often increases consumption of these foods, especially in front of the television (Anschutz et al. 2011). Many times, the food is coated in inedible artifacts such as gloss or shine that superficially make the food more appealing to the eye, an example of a *supernormal stimulus* taking advantage of the mismatch effect. This effect is common across all ages and occurs even in those as young as preschool age (Borzekowski and Robinson 2001). Given that our bodies desired foods heavy in calorie and fat ancestrally, businesses use this practice to appeal to something all humans desire as a result of our ancestral past, or, more specifically, the evolutionary mismatch effect.

Why Sex Sells

Another common example on how our psychological mechanisms are exploited is in the media and the idea that “sex sells.” When it comes to finding mates, males tend to look for physically attractive women who possess indicators that they have good genes and will most likely survive childbirth and be able to produce more than one offspring. Such cues include a small waist-to-hip ratio, good skin, facial and body symmetry, and so on. Most men tend to look for women with these characteristics, yet there is a huge difference between what men (or women!) want and what they get. Although most men would probably like a mate that looks like a model, most men do not end with such a woman for myriad reasons; these attractive women will go for the most attractive males that can offer her the most resources, not to mention that not all women look like perfect models.

The problem arises when we are constantly bombarded by images of attractive females, who not only dedicate their lives to keeping those bodies but who also get photoshopped, thus making their bodies unattainable for the most part. Despite knowing these bodies are unrealistic, they still play on male’s psychological

mechanisms. Kenrick (2011) describes all the negative effects that being exposed to these images lead to. For starters, males who were exposed to several attractive females first and then saw an average-looking female rated this average target as less attractive than males who had first been exposed to several unattractive females. This contrast effect may sound innocuous, yet a later study found that men who were presented with playboy centerpieces reported less commitment and romantic feelings toward their partners than men who had been presented with abstract paintings. Females also fall prey to similar stimuli, albeit in a different way. When it came to physical attractiveness, there were no differences among women who had seen playgirl centerpieces or abstract paintings. However, when the study was replicated using successful, powerful males rather than physically attractive ones, women did report lower commitment and romantic feelings toward their partners after seeing males with resources as opposed to abstract stimuli.

The implications of these studies are enormous because we live surrounded by media that constantly shows us attractive, sensual females and successful, high status males. We are naturally interested in individuals with these characteristics because our ancestors evolved to pursue them because of their high mate value.

Conclusion

Our minds can be easily fooled, and our psychological mechanisms can be tricked. The world in which we live today is plagued by stimuli that mess with our evolved mechanisms in ways we are not consciously aware of. Understanding these mechanisms paves the way to knowing how to activate and manipulate them, a strategy that several companies have mastered in order to better sell their products.

Extended Kin Role

Chelsea Loeffler
Oakland University, Rochester, MI, USA

Synonyms

Complete family unit; Joint family

Definition

The family that extends past the nuclear family of parents could include aunts, uncles, grandparents, and cousins all living nearby or in the same household.

Introduction

Typically when one thinks of extended kin, it includes the grandparents, aunts, and uncles, and in some cases these people could be living in the same household and the nuclear family. The extended kin's role can provide a huge amount of stability in one's life, even if these family members are not seen on a daily basis; the very fact that they are family is enough to keep the relationships in one's life.

Evolution of Extended Kin Role

Since humans typically lived in tribal communities, extended kin facilitated one of the most

crucial aspects of survival, sharing. For example, the male in the family could be hunting without catching anything to eat, whereas the women, children, and extended family members were still able to forage berries and fruit, therefore without sharing, the family unit would go hungry. Extended kin such as grandparents living within the nuclear family was also common as they aided in the gathering of food to feed the family and helped to take care of the grandchildren. Research has suggested that earlier societies were typically very simplistic, usually organized largely by kinship as genetic commonalities (Purzycki 2004). The only real exception for this was in terms of an individual possessing activities such as a shaman or crafting weapons. There has been a link over the decades as researchers see a correlation between extended kin and large brain sizes (Noone and Paper 2015). Research discussed how large extended families has provided for more extensive caretaking during the critical stages of brain development for children. Remarkably, the social environment from larger and more developed clans of humans provided children with more stimuli which, in turn, lead to more advanced mental abilities.

Some believe that there is a "family decline" hypothesis, whereas families are getting smaller, mainly consisting of one mother, one father, and a biological child. Yet, more research is hypothesizing since humans are now living longer than we ever have and the rate of extended kin is becoming more common than it was 100 years ago (Bengtson 2001). For example, culturally, grandparents will move into their children's homes when they are unable to maintain their own and then share in the family responsibilities and functions such as helping to take care of their grandchildren.

Conclusion

Extended kin roles have been important from early human existence with a focus on the survival needs of the community and how sharing impacted that. Extended kin was predominately made up of biological aspects since reproduction was necessary to a tribe survival and "outsiders"

were not commonly welcomed. As we have evolved and are living longer lives, extended kin is still very important to the family unit today. It can almost be viewed as a win-win circumstance where the parents are getting help from the grandparents in terms of the care of their children, and the grandparents continue to feel needed and able to remain social connections as a result.

Extended Phenotype, The

Armin W. Schulz and Marco Polo Camacho
University of Kansas, Lawrence, KS, USA

Definition

The Extended Phenotype by Richard Dawkins is a book widely seen to have made a major contribution towards developing and popularizing the gene-centered view of evolution.

Introduction

In *The Extended Phenotype*, Richard Dawkins supports and motivates two major claims: first, that genes are the proper units of selection and, second, that genes code for phenotypes that extend beyond an organism's skin and into its environment. This entry sketches Dawkins's gene's eye view of evolution, lays out his view of the extended phenotype, and briefly notes some major criticisms of these views.

The Gene's Eye View of Evolution

Dawkins develops the gene's eye view of evolution by drawing a distinction between two kinds of evolutionary entities: replicators and vehicles. According to Dawkins, a replicator is “anything in the universe of which copies are made,” and a replicator is “active” so long as its “nature has some influence over its probability of being copied” (Dawkins 1982, p. 83). Dawkins argues further that genes are the quintessential active replicators: genes are copied across generations, and they also exert influence on their probability of being copied. In particular, through the process of protein synthesis, genes are transcribed into RNA and then translated into proteins (which make up the tissues that determine the organism's phenotype), which, in turn, affects the extent to which they are copied (Dawkins 1982, p. 83).

For Dawkins, though, genes are not the only active replicators: “memes” make up another set of replicators. Memes are units of information that take on physical manifestations (Dawkins 1982, p. 109). If, for example, a given person finds a particular song on the radio appealing, then that person is likely to share this song with a friend, who is then likely to share the song with their friend, and so on. The idea of the song, it might be said, has been copied across individuals and now resides as a unit of physical information in various people's brains. Furthermore, memes influence their probability of being copied; catchier songs, for example, are more likely to be shared (Dawkins 1982, p. 110). However, Dawkins also notes that treating memes as units

of selection may prove to be of secondary importance to evolutionary biology, as it is unclear whether the process of meme replication bears a sufficiently close resemblance to the process of gene replication (Dawkins 1982, pp. 110–112).

Apart from replicators, the other key evolutionary biological entity for Dawkins is “vehicles.” Vehicles are the biological entities in virtue of which genes (or other active replicators) propagate themselves (Dawkins 1982, p. 82). To illustrate this, note that the many phenotypic features of an organism – such as a dove’s wing or a Peregrine falcon’s talons – make it possible for the organism to escape from predators, attack prey, locate potential mates, reproduce, and provide for its offspring; however, these features are replicated only in so far as the genes underlying them are replicated. For this reason, Dawkins does not see these features as replicators in their own right. Still, they are very important, in that they *enable* the relevant replicators to be inherited across generations. Put differently, the replicators reside “inside” these vehicles, and their copying success is determined (at least to a large extent) by the nature of the vehicles they reside in.

With the replicator/vehicle distinction in hand, Dawkins then argues that, by and large, understanding the way biological evolution occurs is best done in terms of genes. The only other option is vehicles. However, when considering the two main types of vehicles in existence – organisms and groups of organisms – it becomes clear that neither of these has the necessary stability to qualify as the basic unit of an evolutionary process. Individual organisms (particular hawks or doves) do not survive for more than a few years (Dawkins 1982, p. 97), and groups of organisms “are constantly blending with other populations and so losing their identity” (Dawkins 1982, p. 100). In this way, Dawkins argues that genes should be made the major focus of evolutionary biological analysis (Dawkins 1982, p. 178).

Dawkins further develops this gene-focused view of evolution by arguing against conceptions of natural selection that make appeal to inclusive fitness, and by showing why apparently Lamarckian phenomena are only Lamarckian on the surface. In short, Dawkins argues that we should see

genes at the center of evolutionary biological analysis, as genes are the only (or at least the major) replicator – and it is replicators that should be the focus of this analysis.

The Extended Phenotype

The second major contribution of Dawkins’s *The Extended Phenotype* consists in the thesis that gives the book its name. Given the above remarks, this thesis can be relatively easily stated.

Recall that, according to Dawkins, genes are active replicators that generate phenotypes (vehicles) to promote their reproduction and survival. Dove genes code for dove wings to promote the survival and reproduction of dove genes. Hawk genes code for hawk beaks to promote the survival and reproduction of hawk genes. Importantly, though, Dawkins thinks there is no reason to see phenotypes as restricted to features on or within the skin of an organism. Indeed, Dawkins thinks that many external features of the environment – such as the nests of the bowerbird – may be regarded as tools “by which that gene could potentially lever itself into the next generation” (Dawkins 1982, p. 199) just like dove wings and hawk beaks. Dawkins calls such traits extended phenotypes, as, unlike dove wings and hawk beaks, these phenotypes extend beyond the organism’s skin into the environment, but like dove wings and hawk beaks, these phenotypes promote the survival and reproduction of genes. Nests, for instance, provide the bowerbird with protection from predators as well as a means for displaying their mate quality, thereby promoting the successful reproduction of the bowerbird’s genes. It is in this regard that nests, then, perform the same function as the bowerbird’s wings and beak. Wings, beaks, and nests may all be regarded as phenotypic tools “by which that gene could potentially lever itself into the next generation” (Dawkins 1982, p. 199).

Dawkins goes so far as to see genes as coding for the behaviors of *other* organisms. Consider parasites, for instance. Nematomorph larvae dwell in host organisms (i.e., bees) and manipulate their bodies to promote their reproduction and

survival. The larvae do this by manipulating bees to dive into water, where the larvae live and develop as worms and the host organism dies (Dawkins 1982, p. 216). In these cases, genes manipulate other organisms to promote their survival and reproduction in much the same way that genes manipulate phenotypic traits to promote their survival. In short, Dawkins thinks that it will frequently make it a lot easier to understand why certain genes are selected for if we see these genes as coding for features that go beyond to skin of the organism (Dawkins 1982, p. 214).

Criticisms

Dawkins' arguments in *The Extended Phenotype* have not been left untouched by critical analysis. To bring out the breadth of the discussion raised by the book, it is now useful to sketch three criticisms that have been of especially great importance in the literature. These criticisms all center on the worry that Dawkins brushes aside non-gene-focused views of evolution too quickly.

The first of these criticisms notes that it appears that Dawkins downplays the importance of vehicles (quite generally) in evolution. It may be true that phenotypes can only be inherited through the genes coding for these phenotypes – however, it is also true that these genes are only “visible” to selection through their phenotypes. Put differently, perhaps *vehicles* should be seen to be at the heart of evolutionary biological analysis, not replicators: what natural selection targets are vehicles – while genes can be used to “keep the books” of the evolutionary process, they are not integral elements of the causal processes making up biological evolution (for more on this criticism, see, e.g., Sterelny and Griffiths 1999).

The second criticism notes that Dawkins appears too rash in presuming that groups of organisms, specifically, are too unstable to be units of selection. Recent work in evolutionary biology has emphasized that the conditions needed for groups to persist long enough to evolve themselves appear more easily satisfied than what Dawkins appears to presume (for more on this

criticism, see, e.g., Sober and Wilson 1998; Okasha 2006; Aktipis 2004).

The third and final criticism worth mentioning here argues that Dawkins has not externalized traditional evolutionary biological analysis enough. To see this, consider the idea of niche construction. Niche construction occurs when organisms construct a niche to promote their reproduction and survival. Put differently, beavers do not just inherit genes for building beaver dams – they inherit the dams, too! Thus, we might criticize Dawkins's view for being too limited in his extensions of traditional evolutionary biological analysis: it is not just that genes should be recognized to have effects that extend into the environment – organisms (and their genes) should be seen as partially responsible for generating that environment in the first place (for more on this criticism, see Odling-Smee et al. 2003).

There is much more that can be said concerning these criticisms – indeed, Dawkins himself has responded to many of them throughout his career (see, e.g., Dawkins 2004). However, all that matters here is noting that, at the very least, there can be no doubt that Dawkins's *The Extended Phenotype* has raised important issues that have furthered the discussion concerning the nature of biological evolution.

Conclusion

Dawkins's *The Extended Phenotype* presents, develops, and extends a gene-based view of evolution. In particular, Dawkins argues that genes, as the key replicators (other than possibly memes), should be seen to be at the heart of the evolutionary process. He further argues that genes should frequently be seen to have phenotypic effects that go beyond the skin of the environment. While his arguments have been criticized – e.g., for not appreciating the importance of vehicles (whether organismic or group-based) in evolution and for not appreciating sufficiently that organisms are often actively involved in generating their environment – there is no doubt that they have made for a significant

advance in the scientific and public understanding of the evolutionary process.

Extended Postmenopausal Lifespan

Austin Jeffery
Oakland University, Rochester, MI, USA

Synonyms

[Postmenopausal Somatic Maintenance](#) [Post-Reproductive Longevity](#)

Definition

It has been proposed that human menopause exists because lifespans have expanded beyond the point of natural reproductive senescence. As a feature of the grandmother hypothesis, this account describes how human females have gained the ability to provide enhanced care to kin.

Introduction

The grandmother hypothesis proposes that the function of postmenopausal (i.e., post-reproductive) life in females is to provide enhanced care to kin. One interpretation of this hypothesis is that postmenopausal life is the consequence of extended human lifespans, living beyond the physiological degradation of reproductive functioning. This interpretation is in contrast with the description of menopause, or the cessation of ovulation, as an adaptation designed to make grandparental care more efficient.

Evidence

Research into the grandmother hypothesis has primarily supported the notion that postmenopausal life is the result of adaptations in somatic maintenance (keeping the body alive), rather than the result of a controlled process of dismantling reproductive capacity in middle age. First, primate reproductive biology suggests that female reproduction is constrained by the number of oocytes, or immature egg (ova) cells, that can develop in the embryonic female. Our closest primate relatives show similar menopausal timing or, at least, begin to show early signs of menopause just prior to their death of old age (Alvarez 2000). This suggests that human evolution has included the extension of life into postmenopause. Second, looking at the human “mortality profile” and modern data on the lifespans and infant mortality of hunter-gatherers, humans have a species-typical age of somatic decline, around 70 years, well beyond oocyte depletion (Gurven and Kaplan 2007). While hunter-gatherers (and, presumably, ancestral

humans) have 30 times the infant mortality of industrial society (driving down their average lifespans), survivorship after the age of 15 is only about a decade short of the healthiest cultures on Earth (72 vs. 85 in Japan). This suggests that longevity is not a consequence of modern lifestyles but a human trait. Third, human life histories are distinct among the primates with later age of maturity, higher annual birthrate, and shorter weaning times (Alvarez 2000). These life history features are predicted by a tradeoff between early developmental speed and longevity, favoring longevity and compensating for the loss of developmental speed by creating a class of grandmother caretakers. The amount of extra lifespan available to humans also appears to coincide with the time needed for a grandchild to reach developmental maturity.

Following menopause, female humans show enhanced investment into kin. There is limited evidence that this investment improves outcomes for children in industrialized societies (Coall and Hertwig 2010; Hawkes 2004) and stronger evidence that child life expectancy in non-industrialized societies is improved by the presence of a maternal grandmother (Strassmann and Garrard 2011). Cross-cultural research demonstrates that maternal grandmothers tend to invest the most, followed by maternal grandfathers, followed by paternal grandmothers, and finally paternal grandfathers (Bishop et al. 2009). This investment tends to flow most strongly towards offspring who show the highest likelihood of surviving and reproducing (i.e., more attractive, healthier, and higher status children; Leek and Smith 1991) and are most assuredly related to the grandmother (are the offspring of daughters or sisters, rather than sons or brothers).

Conclusion

When interpreting the grandmother hypothesis, modern researchers more often adopt the stance that human longevity provided a selective advantage by creating a class of experienced, elderly caretakers, rather than proposing that the cessation of ovulation provided a selective advantage by limiting reproductive options and hazards for the elderly, thus making them better caretakers.

Neighborhood effects; Spillover effects; Spillovers

Definition

Externalities are the “[b]enefits or costs of an individual’s activity that the individual does not receive or bear” (Ekelund et al. 2006, p. 415). They arise whenever the actions of one person affect the welfare of another. There are positive (when others receive a benefit) and negative (when others are burdened with costs) externalities that may arise from production and consumption decisions. When the production or consumption of a good carries externalities, the effects spill over outside of the market and consequently are not fully reflected in the good’s price. Widespread consumption of schooling leads to a reduction in the crime rate, a positive externality (Lochner and Moretti 2004). Steel production generates air pollution, a negative externality. You receive a benefit living among educated citizens and you pay a cost living downwind of a steel plant, but neither is likely to influence the market price of schooling or steel without some coordination or intervention (for reasons discussed below). The production or consumption of a good can result in multiple, potentially opposite externalities with varying effects across a population. Air pollution from steel production will harm those with respiratory illnesses more than their healthy neighbors and may even benefit air-filtration salespersons. One can frame most negative externalities as positive externalities, or vice versa, by flipping the spillover’s reference

point. For example, air pollution is a net-negative externality from steel production, and cleaner air is a *positive* externality of *reduced* steel production.

Introduction

While the concept of externalities is not controversial, their consequences for market efficiency, and resultant recommendations for policy interventions, have spurred a wealth of research and considerable disagreement among academics and laypersons alike.

Failing Markets and Policy Responses

Market Failure

Pareto efficiency, or so-called social welfare maximizing outcomes, wherein no individual can be made better off without someone else being made worse off, is a common goal for welfare economists (though it is not necessarily sufficient for a normatively appealing distribution of resources) [A]. Provided a host of conditions are met, competitive markets arrive at such outcomes. One of these conditions is that the costs or benefits from producing/consuming a good accrue only to the decision-maker – that is, there are no externalities. In the presence of externalities, the market “fails” to maximize social welfare as individuals are driven to underproduce/consume goods with positive externalities and overproduce/consume goods with negative externalities. Although Pareto efficient outcomes are still possible, the market *by itself* will not arrive at that distribution of resources.

To see why this happens, consider that individuals strive to maximize their welfare, broadly conceived [B]. They do this by engaging in a desired action until its *private marginal benefit* equals its *private marginal cost*. At that point, net benefit is zero, and additional production/consumption is undesirable as most actions have increasing marginal costs and decreasing marginal benefits [C]. Absent externalities, an action’s *social* marginal costs and benefits – its private marginal costs and benefits summed across all affected individuals – are the same as its private

marginal costs and benefits because the decision-maker is the sole beneficiary of her action. Not so in the presence of externalities when private actions help or hurt outsiders, too. With positive externalities, an action's social marginal benefit is greater than its private marginal benefit. If individuals do not consider the public ramifications of their decisions, markets will promote *underproduction/consumption* of the good or service in question (e.g., too few vaccinations) because the decision-maker *bears all the costs* of her actions but *shares their benefits*. With negative externalities, an action's social marginal cost is greater than its private marginal cost, and the market will promote its *overproduction/consumption* (e.g., too many people texting while driving) because the decision-maker *reaps all the benefits* of her actions but *shares their costs* across society. In both instances, the market has failed to deliver the (economically defined) optimal outcome.

Government Responses to Externalities

To increase social welfare, public policymakers seek to correct externality-caused market failures with a variety of instruments, each with their own (dis)advantages, enthusiastic champions, and vehement opponents [D]. Among the most politically heated, governments can counteract the under-/over-provision of positive/negative externalities through "command-and-control" tools, mandating a specific level or method of the good's production/consumption for each actor and levying fines if standards are not met. In the United States, the Affordable Care Act (ACA, aka Obamacare) was such an attempt, aimed at enrolling in health insurance – with its positive social spillovers – citizens who were either unable or unwilling to purchase it. The ACA's "individual mandate" requires individuals to purchase health insurance or face a fine. When policymakers deem externalities sufficiently large, government agencies may take over production to fully regulate the spillovers, as is the case with single-payer healthcare in countries such as Canada, the UK, and France. Although command-and-control approaches inspire strong ideological- and efficiency-based criticisms, there are instances when these tools provide the most (cost-) effective solutions (Cole and Grossman

1999). As such, the question is not whether to employ command-and-control but under what circumstances.

Policymakers can also rely on market forces to improve social welfare by (i) artificially aligning private and public marginal costs and benefits via a per-unit tax or subsidy on the externality or (ii) capping an externality at the socially optimal level and then allowing producers/consumers to trade rights to produce/consume the externality among themselves. These "market-based" instruments rely on government agencies to set the price or the quantity of the externality but let the market reduce compliance costs [E]. For example, a Pigouvian tax forces steel mills to internalize the social cost of their production externality by taxing each ton of air pollution they generate. The value of that tax will equal the difference between (i) the marginal cost of one ton of pollution to *society*, which is relatively high, and (ii) the marginal cost of one ton of pollution to *the mill*, which is relatively low. Making the mills cover the full cost of their actions yields efficient production decisions (Pigou 1920). Similarly, cap and trade systems mandate the amount of an externality that an industry may produce but then allow producers within that industry to efficiently distribute externality production among themselves through a market. For example, in the 1990s, the Environmental Protection Agency (EPA) capped the amount of sulfur dioxide the US energy industry could emit. It then distributed emission permits to the individual energy providers, who could trade those permits, meaning providers who found it cheapest to reduce emissions could sell their permits to higher-cost emitters. This approach resulted in more cost-effective emission reductions than would have occurred via command-and-control (Keohane 2007).

In general, market-based interventions are more cost-effective than strict command and control because the most efficient actors will be the ones to achieve the abatement in negative externalities or the provision of positive externalities. The distribution of regulatory burden is different from that of command-and-control approaches, which mandate individual targets (Baumol and Oates 1988). In addition, market-based

instruments encourage *innovation* as there is now an incentive to lower the cost of reducing/producing a negative/positive externality. However, for a number of reasons, market approaches have not always received the widespread application that these benefits might warrant [F].

Market-based interventions are attractive, but humans systematically deviate from the rational actor models that undergird them (Kahneman 2011). Policymakers can leverage these deviations from rational behavior by restructuring the decision-making environment (without limiting options available to the decision-maker) so that it nudges people into making choices that improve their and society's welfare (Thaler and Sunstein 2008). For example, individuals often struggle to align their immediate preferences and behaviors with their long-term goals. Consequently, relatively few individuals join employer-offered retirement saving programs despite their long-term advantages, and many who do participate do not save enough for the kind of retirement they want. The cognitive and disciplinary demands of forgoing present consumption for greater future consumption are challenging even for people who care about their retirement. But what if the decision were reversed? Policymakers can make saving, rather than deciding on whether and how much to save, the default so that individuals have to opt out rather than opt in. Automatically enrolling employees in such programs and periodically increasing the minimum contribution rate substantially increase retirement savings (Benartzi and Thaler 2013). This carries benefits for savers because their lifetime consumption is now more even across time, and it benefits their compatriots by reducing the costs of communal elderly care. Policies of this sort, which rest on the growing cognitive and behavioral science literatures, highlight the importance of nuanced institutional design to individual and social welfare (Ostrom 2009), thus expanding the debate beyond state versus market and market instruments versus command-and-control [G].

Coasean Bargaining

Because government is not subject to the same profit-based efficiency motivation as industry, and

because calculating private and social marginal costs and benefits can be difficult, some academics argue that government intervention may be worse than the market failures it tries to correct. In situations where enforceable property rights exist and there are few barriers (i.e., "transaction costs") to individuals bargaining, parties affected by externalities may resolve market failures themselves, without recourse to the interventions discussed earlier (Coase 1960). To illustrate this approach, consider if our steel mill was located upstream from a fishery. In the absence of regulation, the steel mill imposes a negative externality on the fishery in the form of water pollution. If, however, the fishery possesses property rights over clean water, its owners can demand compensation from the steel mill for the damages to their fish stock. The steel mill is thus forced to include in their production decisions the marginal cost that their behavior imposes on the fishery, thereby aligning private and social marginal costs and benefits and ensuring an efficient market outcome [H]. Here, government's role may be limited to establishing and maintaining the conditions under which the market can overcome potential failures. Among these conditions are well-defined property rights, rule of law, and so forth. There exist, however, many situations where property rights are difficult to enforce, or where transactions costs are high due to numerous parties involved in negotiations, such that efficient outcomes may require more extensive intervention.

Externalities and Cooperation

Externalities are essential to understanding cooperation (or lack thereof) on matters of social import. Free riding on others' efforts or investments is often a winning strategy when externalities are present, making cooperation difficult. To illustrate, let us return to the Coasean bargaining example, but with a twist: the steel mill, now with rights to pollute the river, finds itself upstream of *numerous* fisheries all equally affected by its pollution. No fishery alone can compensate the steel mill for its reduced production; they must cooperate to raise sufficient funds. All of the fishery owners want a

cleaner river, but each knows she will enjoy its benefits *whether or not* she contributes toward the mill's compensatory sum, so long as that sum is reached. The environmental improvement is a positive externality and its benefits non-excludable. Its costs, however, can be shared and shirked. The fisheries benefit most overall if all fisheries pay to compensate the steel mill to reduce pollution as much as possible, but each fishery owner has an incentive to *free ride* – withhold her funds and hope that the other owners will make up for her lost contribution [I]. Because all the fishery owners have the same incentive to free ride, there is a real possibility that the fisheries will not raise enough funds to stop the mill's polluting, making everyone worse off than if all or even a few fisheries had shouldered the financial burden. Game theory predicts that there is little chance of cooperation in social situations centered around such externalities – discouraging given the number of situations that display this general incentive structure (e.g., charitable giving, open-access computer code, environmental resource management, student group projects, etc.) [J].

Remarkably, the externality-borne incentives at the heart of the market failures discussed earlier are the same as those leading to the cooperative breakdowns just laid out. (Technically, defecting in a prisoner's dilemma constitutes a market failure and full cooperation the Pareto optimum.) When studying cooperation, however, researchers focus less on externally imposed market corrections (such as command-and-control tools or market-based instruments) in favor of studying the conditions under which cooperative success might be achieved endogenously (i.e., from within the system as it already exists), often via group-imposed incentives. For instance, behavioral economists and psychologists research the conditions under which individuals are willing to cooperate in creating/reducing goods with positive/negative externalities (e.g., see Chaudhuri 2011), finding that individuals vary widely in (i) their proclivities to cooperate (e.g., Fischbacher and Gächter 2010) and/or (ii) in their expectations of how others might respond to cooperation on their part. For example, some display ostensibly altruistic behavior (i.e., cooperating regardless of what others are doing)

or conditionally cooperative behavior (i.e., cooperating if others are too), suggesting that cooperative success is not impossible [K]. Even when group composition is not favorable to cooperation (e.g., when few altruists are present), institutional settings (e.g., how much oversight there is, whether punishment is possible, how benefits are distributed, etc.) can discourage free riding on others' efforts to produce/reduce goods with externalities (Ostrom et al. 1994). These institutions then mirror, in part, the exogenous market corrections implemented by government officials, albeit with more reliance on self-governance.

Conclusion

While the theory on externalities is well established, the real-world implications are, unsurprisingly, controversial. Externalities are prevalent in society – few decisions do not impact those around us. But society often struggles over whether and how to address externalities. Strict economic efficiency analyses, probably the most common approach to evaluate how to tackle externalities, may not be sufficient to make policy decisions – in part because analyses on the cost-effectiveness of solutions to problems that arise out of externalities often disregard costs and constraints that go beyond economic considerations, such as political realities and societal preferences (Richards 1999). There are a variety of reasons why society might often prefer one approach over a more efficient one.

Further, there is often disagreement over whether something constitutes an externality in the first place. People will disagree over how “public” a problem is. The recent debate regarding gay marriage demonstrates this well. Some advocates argue that no one but the consenting individuals marrying are affected by the ability to lawfully wed, while opponents argue that such relationships spill over to them, undermining their own heterosexual coupling. Moreover, some people may view gay marriage as a right (constitutional, human, or otherwise). In this case, these individuals will argue that economic efficiency criteria are irrelevant – the debate over whether externalities exist ceases to be of importance. Additional philosophical issues arise in the debate over whether animal welfare in, say, food

production or product testing constitutes a negative externality even though humans are not directly affected. If so, does it warrant increased regulation with potential impacts on the cost of food and welfare implications for food producers?

Externalities exist, and economic theory gives us many of the tools to assess and regulate their efficient distribution. However, the realities of designing effective policies are complicated, in part because of the difficulty of grappling with the underlying questions about how to conceive of goods and how far afield we are willing to look for their impacts.

Connections and Extensions

[A] Well-functioning markets arrive at a Pareto efficient resource distribution, of which there may be many, but there is no guarantee that the specific distribution of resources is politically or morally palatable. In addition, the “liberal paradox” shows the impossibility of achieving Pareto efficiencies while respecting individual liberties.

[B] The classic rational choice model of human decision-making allows individuals to receive (dis) utility from numerous and often nonpecuniary sources such as social standing, kudos from others, the warm fuzzy feeling you get from sharing/voting/volunteering, etc. and is thus broad in its view of what motivates individuals to act. However, it does posit (at times unrealistically) that actors have the time, desire, and cognitive capacity to calculate the costs and benefits associated with available actions, allowing them to choose the course that results in maximum net utility. Consequently, researchers have identified instances when individuals violate the classic model’s assumptions and behavioral predictions (Kahneman 2011), and subsequent extensions to the rational choice approach have incorporated general and context-specific bounds on human cognition. Still, given the model’s intuitive appeal, its mathematical tractability, and its ability to provide clear and, in some cases, accurate predictions, the classic rational choice model remains at the core of public policy analysis.

[C] “Marginal” means consuming or creating a single unit of a good or service on top of what already exists. For example, building an additional

floor in a skyscraper costs more than the last because it requires reinforcing the foundation and lower levels (increasing marginal cost), and eating an additional scoop of ice cream yields less joy than its predecessor (decreasing marginal benefit). [D] Market failure stemming from externalities and their subsequent violations of the Pareto conditions is one of the main motivations for public policy intervention in the economy, along with lowering transaction costs and changing resource allocations on moral grounds (Weimer and Vining 2017). However, there are several requirements for Pareto efficiency beyond those related to externalities, and they also frequently go unmet. Thus, almost all markets exhibit market failure to varying degrees, and economists and policymakers spend much time and effort determining *which* market failures government should try to correct.

[E] Compliance costs refer to the resources (e.g., time and money) spent by industry (or individual consumers) to comply with a given regulation.

[F] Among the reasons for the relative lack of market-based instruments are industry opposition to regulation generally, regulator experience with command-and-control over market-based instruments, and legislators—who are often trained lawyers—preferring policy rooted in law rather than economics (Stavins 1998).

[G] It is important to distinguish between the state versus market debate and the market instruments versus command and control debate. The first contests whether government should intervene at all. Contrast this with the second debate, where the issue is not intervention per se, but what form the intervention should take. Market-based instruments are still government interventions, but do not mandate individual behavior as command-and-control would.

[H] Efficient market outcomes are not contingent upon which party holds property rights (Coase 1960). If the steel mill has property rights over the water, then the fishery pays it to reduce its pollution, but the final level of pollution will be the same as when the fishery holds the rights.

[I] This assumes constant marginal costs and benefits of pollution reduction.

[J] Scenarios like these, where community welfare is at odds with individual incentives, are called

“social dilemmas.” To study behavior in these settings, researchers often abstract these scenarios as n-player prisoner’s dilemmas and public goods games.

[K] Evolutionary game theory provides justification for why these preferences may exist despite these preferences often leading to less desirable outcomes for the individual. In repeated games, cooperating when others cooperate can lead to mutually beneficial outcomes over mutual defection, thus suggesting that evolving cooperative strategies and preferences may provide an advantage (Axelrod 1984).

Extinction

Christoforos Christoforos

Synonyms

[Behavior elimination](#); [Behavior that became extinct](#); [Extinguished response](#)

Definition

Extinction is a functional process through which a behavioral response is loosened and ultimately becomes extinguished due to the absence of conditioned and/or operant reinforcement.

Introduction

Ivan Petrovich Pavlov was the first who theoretically and operationally designated and described

the behavioral process that is widely known as extinction through his work on conditioned reflexes (Ramnero and Torneke 2011), specifically, in a well-known experimental procedure that I. P. Pavlov had conducted, where dogs were classically conditioned to secrete saliva and digestive fluid in response to the sound of a bell which had consistently proceeded their usual food (i.e., meat powder). When the dogs acquired the classically conditioned association between a meat powder (i.e., unconditioned stimulus) and the sound of a bell (i.e., conditioned stimulus), the sound of the bell was consistently presented to them in the absence of the meat powder, leading the conditioned response of saliva and digestive fluid secretion to be loosened and ultimately to become extinct (Shanks 1995).

Contemporary Definition of the Term Extinction

In the contemporary literature related to learning, the term extinction is used to designate and define the progressive weakening of behavioral responses as well as the experimental techniques which set the ground for this functional process (McSweeney and Murphy 2014). The behavioral process of extinction has come to be one of the most well-examined behavioral mechanisms in the fields of both responded and operant conditioning (Staddon 2014). This tremendous interest for the process of extinction is to some extent due to its clinical significance. Specifically, it has been consistently cited that the functional principles that governed the process of extinction constitute the underlying foundation of therapeutic interventions that are widely applied to treat anxiety disorders, substance abuse disorders, and other behavioral abnormalities (McSweeney and Murphy 2014).

Functional Qualities of the Extinction as a Behavioral Process

Extinction is a multifaceted behavioral mechanism that has been recently found not to remove the initial leaning experience (Schmajuk 2010). For instance, I. P. Pavlov indicated through his

work on conditioned reflexes that the reaction that became extinct has the capacity to be reactivated in a future time, a phenomenon that is termed as “spontaneous recovery” (Schachtman 2011). Subsequently, the functional phenomenon of “spontaneous recovery” has been experimentally verified in the fields of both respondent and operant conditioning (McSweeney and Murphy 2014). However, the phenomenon of spontaneous recovery does not always appear and when it does appear it is usually for a short period of time. In addition, when the phenomenon of spontaneous recovery takes place the conditioned and/or operant behavioral response is of lower intensity than it used to be before it became extinct (Staddon 2014).

As already mentioned the behavioral process of extinction reflects the elimination of formerly received unconditioned stimuli and/or reinforcers, yet it also reflects the lack of a contingency between a reaction and a reinforcer and/or between a conditioned and an unconditioned stimulus (Spence 1978). Declarations such as extinction comprised of eight appearances of the conditioned stimuli in the absence of the unconditioned stimuli and/or extinction took place due to reinforcers’ elimination depicts this utilization of the term extinction (Klein and Mowrer 1989).

At an operational level, the process of extinction designates the reduction of reactions from higher intensity as detected previously to extinction, to lower intensity after the application of one of the aforesaid processes (Schachtman 2011). Declarations such as the conditioned response became extinct, and responding by the 8th trial depicts this utilization of the term extinction. Despite the fact that this procedural result is widely demonstrated, it is subject to specific qualifications (Schachtman 2011). Firstly, the amount of time and the operational degree of reactions’ elimination relies to a high extent on the way that the procedural conditions of extinction changed from the ones formed prior to extinction, that is, while the reaction was first acquired and maintained. Secondly, even though, a reaction that has become extinct has the potential to be fully eliminated, there are various environmental conditions that could set the ground in such a manner that its reactivation at least to some extent is fairly possible. In addition, when it comes to

outcomes, simultaneously with decreasing the learned reaction which constitutes the aim of the extinction, the process of extinction might also trigger the activation of additional reactions (McSweeney and Murphy 2014). Yet, if the additional reactions that have been triggered by the extinction process do not receive either operant and/or conditioned reinforcement they would be a temporary result, and eventually vanish.

A Theoretical Conceptualization of the Term “Behavioral Extinction”

Theoretically, the term extinction designates and describes a behavioral process of functional nature. Declarations such as extinction’s operational mechanisms of inhibitory nature did not remove the initial learning outcome, which depicts this utilization of the term extinction (McSweeney and Murphy 2014). In addition, similarities among behavioral effects indicate associated underlying mechanism between classical and instrumental extinction. Moreover, some theoretical perspectives related to extinction directed mostly their attention on either external processes or on internal processes (Schachtman 2011). Specifically, on the one hand behavior-analytic theoretical perspectives of instrumental extinction directed mostly their attention on external processes, that is, the ones that could be observed and measured. On the other hand, the associative theoretical perspectives of classical and instrumental extinction directed mostly their attention on internal processes, that is, the ones that could be inferred (Shanks 1995).

The Role of Prediction Error in the Behavioral Process of Extinction

Most of the current theoretical perspectives related to learning propose that the behavioral process of extinction is governed by the error correction process, a conceptualization that became widely known through the classical conditioning model of Rescorla-Wagner (McSweeney and Murphy 2014). This model

claims that learning takes place when an unconditioned stimulus is surprising enough for an organism. In addition, this model proposes that the presentation of the conditioned stimulus in the absence of the unconditioned stimulus during the extinction process is surprising too. In addition, in order for the prediction error to be fixed, the classically conditioned association of the conditioned–unconditioned stimulus presentation is loosening till the conditioned stimulus precisely foresees the no unconditioned stimulus result. Given an adequate quantity of extinction, this model presumes that the force of an association could be fully extinguished (Schachtman 2011).

Conclusion

The term extinction is used to designate and define the progressive weakening of behavioral responses as well as the experimental techniques which set the ground for this functional process. In the last two decades, the functional processes and qualities of the extinction have been extensively researched (McSweeney and Murphy 2014). Contemporary research related to extinction has consistently proposed that extinction does not remove the initial learning outcome. Specifically, there is high level of consensus in that the behavioral process of extinction depends to a high extent on a new form of learning which is either interfering and challenging or inhibiting the initial learning outcome (Schachtman 2011). Additionally, the context in which the process of extinction operated constitutes a significant variable when it comes to the formation and preservation of the extinction outcome (Staddon 2014). Extinction constitutes a functional procedure and a behavioral mechanism which is highly important in order to empirically and theoretically examine learning outcomes and their actual implementation. In-depth knowledge of the way that the behavioral dynamics alters over the course of the process of extinction is crucial as it sheds light on various phenomena of classical and instrumental conditioning related to the acquisition and preservation of associations (McSweeney and Murphy 2014).

Extinction of Neanderthals

Olivia Jewell
SUNY New Paltz, New Paltz, NY, USA

Synonyms

[Death](#); [Elimination](#)

Definition

The process of coming to an end or dying out, annihilation, being extinguished.

Introduction

Between 60 and 40 thousand years ago (kya), during a time period known as Marine Isotope

Stage 3 (MIS-3), the species *Homo neanderthalensis*, or, Neanderthals, disappeared. There is still debate around what caused their disappearance. The two hypotheses that have garnered the most research and attention are climate change and competition with modern humans. The first uses changes in the environment as the cause of Neanderthal extinction, especially considering how many there were, and how drastic they were during the period (Finlayson and Carrion 2007; Jimenez-Espejo et al. 2006). The second argues that a more likely explanation of Neanderthal extinction comes from either direct or indirect competition with modern humans (Banks et al. 2008). Naturally of course there is also the argument that both of these factors influenced Neanderthal extinction in their own ways.

In general, the time period that is focused on in research about Neanderthal extinction spans between 20,000 and 60,000 years ago (Gilligan 2007; Stewart 2007). However, it is suspected that Neanderthals will have disappeared from different areas at different times. It is likely that the forces that influenced their eventual extinction (not simply local extinction) will have been due to some combination of the factors listed above (Smith 2013). The following entry elaborates on the morphology of Neanderthals, and the environment they lived in, in addition to describing the main theories that surround this mysterious extinction.

Neanderthal Morphology

It is crucial to understand that Neanderthals were built differently than the modern humans we see today. Their bodies were much thicker, their limbs shorter, and their faces protruded more around the nose and jaw area. Various hypotheses surround what selective pressures caused them to adapt this way. The main theory describes the cold temperatures that they lived in and suggests that their morphology was suited for surviving very cold temperatures (Smith 2013; Gilligan 2007; Stewart 2007). While the climate did oscillate during the Neanderthal habitation of Western Europe, the past 80,000 years of their inhabitation would have been much colder than previous eras (Smith 2013).

Their thick bodies were presumably to preserve heat, broad noses were meant to allow for expanded oxygen intake, and shorter limbs helped to preserve circulation (Smith 2013; Gilligan 2007; Stewart 2007). These adaptations also made Neanderthals very powerfully built, with strong bones and large amounts of muscle across the body. While other modern humans were also built for power, the morphology of Neanderthals remains unique partly due to the extent to which they were so powerfully built but also because they were so well adapted to cold, much more so than anything we see in modern humans (Smith 2013).

The large size and cold adaptiveness suggests that a Neanderthal lifestyle would have necessitated a high-protein diet, especially because of the frigid temperatures (Smith 2013). A high-protein diet requires a large amount of hunting, an activity that could have easily taken up most of an individual's day. Another theory surrounding the morphology of Neanderthals concerns their hunting environment.

Neanderthals lived in climates that were more closed off, unlike the warmer and more open climates associated with modern humans (Stewart 2005). This closed habitat would not have necessitated long-distance running, meaning that longer limbs would not have been selected for. Together, the colder climate and the closed nature of the environment would likely have selected for shorter distal limbs. Their thick bodies may have also served to aid Neanderthals with carrying large amounts of hunted material, as well as simply surviving the rigorous activity that was hunting in itself (Stewart 2005). These hypotheses are certainly plausible compared with the theories on thermoregulation; it is important to remember that while an adaptation may have been selected for a given reason, it can still serve to aid the animal in a variety of ways beyond that reason.

Climate Change

If Neanderthals were so well-adapted to the cold weather of Western Europe, how could colder temperatures have caused them to go extinct. An important detail, according to Stewart (2005), is that each climactic era, and the transition between

them, is different, and just because the Neanderthals had survived previous eras, does not necessitate that they would be equipped to survive all of them.

Climate change can have a drastic impact on a variety of species that live in a particular habitat, even in ways that are not simply due to the changes in temperature. Issues from drastically changing habitats, to causing decreases in pollinator species, or increasing populations of pathogens, can all be caused by climate change. A review of climate change and its impact on species can help illuminate just how it can have such drastic effects on different populations, leading to the eventual extinction of some (Cahill et al. 2013).

MIS-3 was an era of drastic climactic variation and overall cooling of the environment, as the world approached the Last Glacial Maximum (LGM) which would have caused severe temperature drops as well (Smith 2013; Stewart 2007, 2005). Naturally one important and somewhat obvious problem caused by climate change is the potential for new temperatures to be outside of the survivable range for a particular species (Cahill et al. 2013). Neanderthals were typically cold-adapted; however, if temperatures managed to get much colder at the beginning of the LGM, it may have posed a challenge for them. Not only was the air cold, but increases in wind and wind bursts around this time could have also made a difference in temperature and climate. The increase in wind likely also increases dust and thus makes the climate more arid and less livable (Gilligan 2007).

These changes would have severely limited their ability to move around outside shelter to do things like hunt for food. Gilligan (2007) notes that there is very little evidence of Neanderthal clothing, and it is assumed that because their bodies were already adapted to cooler climates, they would not have a need for large amounts of external clothing. He points out that this would have been precisely the problem, if the temperature dropped quickly enough to prevent them from finding adequate covering, lack of clothing could have made the harsh climate potentially lethal.

Neanderthals may not have been the only mammals that suffered due to these drastic climatic changes, especially since it is clear that climate change can have an effect on several species (Cahill et al. 2013). In a comparative analysis of other large fauna that were extant during MIS-3, Stewart (2007) provides evidence to suggest that Neanderthals were not the only large, cold-adapted mammals to go extinct during this time. This suggests that this transition into the LGM and the resulting changes in temperature and environmental conditions would have been difficult to survive for many different creatures, making it more likely that it could have precipitated or encouraged the extinction of the Neanderthals as well. Some of these other species to go extinct included the wild cat, the Iberian lynx, leopard, hyena, and antelope (Stewart 2007).

It appears as though one of the most compelling reasons for climate changes causing extinction is related to the loss of potential prey and food as species go extinct, potentially causing other species to go extinct as well. This seems to be the most common cause of species extinction (Cahill et al. 2013). As these other mammals went extinct, Neanderthals may have suffered from a lack of food resources, which would have encouraged their move toward extinction (Cahill et al. 2013).

There is evidence that suggests that Neanderthals were able to adapt to some climate changes; however, abandonment of sites as well as local small-scale extinctions was not uncommon in their history as certain areas became potentially uninhabitable. We do know that they survived for quite a while during a period of varying climate, which suggests a degree of adaptiveness, but in the end there may have been other factors, or it simply was not enough (Jimenez-Espejo et al. 2006).

In general the area around the Iberian Peninsula would have produced an environment huge in biodiversity, but also high in levels of climatic variations, especially with the presence of Heinrich Events and Dansgaard-Oeschger Events (Jimenez-Espejo et al. 2006). Archeological evidence indicates that caves in Southern Iberia may have been the last remaining habitat for extant

Neanderthals until about 28,000 (Jennings et al. 2011). This area featured a climate with high variability in rainfall and temperature, which created several different environments that would have been suitable for Neanderthal populations. Based on the numbers of archeological sites in these areas, it appears that Neanderthals tended to prefer climates that were either warm/wet or cool/wet, with large amounts of rainfall. The last few Neanderthals lived in areas that typically received between 400 and 600 mm of rain each year, but as the climate changed, their habitats became broken up as rainfall decreased. It is possible that the increase in isolation between these groups as rainfall decreased could have promoted their eventual extinction (Jennings et al. 2011). This would have been around the time when anatomically modern humans were migrating into the area, as the climate of the area was shifting, which of course brings about the hypothesis that modern human migration impacted the extinction of the Neanderthals.

Competition with Modern Humans

It is currently believed that Anatomically Modern Humans (AMH) evolved in Africa and then migrated outward at some point well after 80,000 years ago (Smith 2013). One group of researchers suggests that as AMH populations migrated into the Iberian Peninsula, they began to push the Neanderthal populations living there further south down the peninsula. This would have been just before Heinrich event 4, which was a period during which icebergs collapsing into the North Atlantic caused decreases in North and Mid-Atlantic sea temperatures, cooling the environment (Banks et al. 2008; NOAA 2008).

Climate research that has focused on some of the last climatic events Neanderthals would have seen before going extinct indicates that the areas to the North of the Iberian Peninsula, where they were settled primarily at that time, would have been of mild climate, indicating that had the Neanderthals wished to expand Northward, they could have done so without climate being an issue. Overall, this contradicts the idea that climate would have been the main or only driving force

behind Neanderthal extinction, since they may have had an option that kept them out of the cold. The encroaching AMH population into the Iberian Peninsula can then be the only suitable explanation for Neanderthal Extinction, per Banks et al. (2008).

This study illustrates, not the reasons why competition may have led to extinction, other than the assumption that if AMH and Neanderthals were living in the same areas, AMH would win; however, it is saying that climate alone would not have been the force that drove the Neanderthals to their eventual end.

However, Gilligan (2007) points out that there is little evidence to date that supports the idea that tool use in humans made them objectively superior in terms of food procurement, meaning that it was unlikely that they out-competed the Neanderthals. Assumedly, the Neanderthals in the region would have been plenty successful at hunting and gathering, and there is no reason that modern human success would necessarily disadvantage them (Gilligan 2007). In addition, Villa and Roebroeks (2014) found no archeological evidence to convincingly suggest that the modern humans living near or around the Neanderthals were superior enough to have caused their extinction.

To a certain degree, every environment will have different species' who are competing for resources (Faria 2007) and the MIS-3 environment with AMH and Neanderthals would have been no different. The question is whether or not their competition for resources was intense enough to lead to the extinction of the Neanderthals, in the absence of other challenges.

It is also suggested that while AMH and Neanderthals may not have been in direct competition with each other, the stronger genes, higher fertility, and greater intelligence may have simply allowed the modern humans to be more adaptive to changing environments, leading to the replacement of the Neanderthals (Faria 2007). This theory suggests an extinction pattern that merely coincided with AMH migration into the area, and less an active annihilation by the modern humans. It is possible that the addition of culture to a human population

made surviving the cold easier for AMH and could have caused them to outcompete the Neanderthal's biological adaptations of being robustly built. Additionally, if the Neanderthals needed to spend more energy keeping warm as the environment became colder, they had less energy for hunting or other important survival activities, including reproduction (Smith 2013).

In a model created by Faria (2007) it is illustrated that none of the hypotheses, competition, replacement, war, or disease, could have been sufficient for the extinction of Neanderthals, either when taken alone or when analyzed together. This clearly indicates that there must have been other forces at work to drive the Neanderthals out completely.

Assimilation

A hypothesis that falls under this umbrella of theories surrounding Neanderthal extinction at the hands of modern humans is the assimilation hypothesis, which essentially states that Neanderthals and modern humans interbred enough that as the "pure bred" Neanderthals died out, all that was left was modern humans with trace amounts of Neanderthal DNA, evidence for which we still see today (Smith 2013). Shea (2008) notes that any time you have populations intermingling there is bound to be reproduction between the two, which suggests a certain degree of cooperation as well.

There is evidence to suggest that there is a fraction of the modern human genome, especially for those with ancestry in Western Europe, that is Neanderthal in origin (Smith 2013). This provides provocative evidence that when modern humans migrated into Western Europe, they did not simply replace or wipe out the Neanderthals, there must have been some interaction between the two in other forms for our genome to turn out this way.

In general modern human populations at a given site were larger than Neanderthal populations at another site. So overall, modern humans had several advantages over Neanderthals, those included living in larger groups and having fitted clothing to protect from the cold.

Smith (2013) proposes that while modern humans likely came into the area, interbred with a small portion of Neanderthals that were left, and the Neanderthal DNA became slowly incorporated and soon diluted by the vast number of modern human DNA that it was competing with.

It is possible that after interbreeding with *Homo sapiens*, their genes became dominant and led to them outliving Neanderthals (Faria 2007). Various ideas have been proposed that capture Neanderthal extinction within the whole picture of human evolution. It is possible that modern humans migrated and replaced the Neanderthals or that they lived together and cooperated for many years (Stringer 1990; Wolpoff 1989). Other ideas are a mixture of these two, suggesting that neither is a complete picture of what may have really happened (Faria 2007).

Conclusion

Overall the main cause of Neanderthal extinction would have likely been lack of resources, and it is unlikely that one and only one source contributed to this. The above theories discuss different means by which either climate change or interference by AMH populations could have helped to create this lack of resources. One example being that as the climate became colder and other mammals began to die out, Neanderthals no longer had a viable food source, which caused increased mortality and decreased fertility (Gilligan 2007).

In a comprehensive review of climate change and its effect on animal populations, it is pointed out that it does not make any sense to regard climate change as the sole cause of extinction. As climactic patterns fluctuate, creating changes in the environment, animal behaviors change as resources change in availability, which will absolutely have an effect on all of the fauna in a particular habitat (Cahill et al. 2013).

The migration of the modern humans may not have directly killed off the Neanderthals, especially since there is strong genetic evidence that they interbred with each other (Smith 2013). However, the modern human cultural adaptations like tools and, most importantly, fitted clothing may have

contributed to their increased ability to survive. In addition, as they began to interbreed with Neanderthals, it is possible that slowly the last few “pure-bred” Neanderthals began to die out (especially if their prey was also dying out) leaving the only remaining pieces of Neanderthals as fractions of our modern human genome (Smith 2013; Faria 2007).

Alas, while we do not have Neanderthals wandering the earth the way they would have done thousands of years ago, for many, there is a small part of the Neanderthal genome that is still alive and with us today.

food sources (susceptible to extraction from a matrix or a case).

Introduction

The Extractive Foraging Hypothesis (EFH) is one of three interrelated hypotheses, first proposed by Parker and Gibson in 1977, about object manipulation and tool use in nonhuman animals. It states that *intelligent tool use* arose as an adaptation for *extractive foraging*, i.e., exploiting a variety of seasonally limited, local, high-energy, embedded food sources. The hypothesis further states that increased brain size of great apes and hominids arose as part of this adaptation.

Definition

Intelligent tool use arose as an adaptation for *extractive foraging*, i.e., feeding on embedded

A Taxonomy of Object Manipulation and Tool Use

Parker and Gibson (1977, 1979) proposed three distinct hypotheses about object manipulation and tool use in nonhuman animals. First, they suggested a taxonomy of object manipulation (including simple prehension, simple object manipulation, object-substrate manipulation, complex object manipulation, and social-object manipulation), and on the basis of this taxonomy they distinguished between *intelligent* and *context-specific* tool use. Both taxonomies, of object manipulation and of tool use, have been derived from Piaget's (1952) theory of sensorimotor stages in human infants.

The second hypothesis addresses the *evolutionary origin* and *functional significance* of intelligent tool use in the nonhuman animals. The authors claimed that *intelligent* tool use arose as an adaptation for *extractive foraging* and feeding on a variety of seasonally and locally variable encased foods. In contrast, *stereotyped* tool use is associated with *context-specific* foraging on a single nonseasonal food source. The latter form of tool use also correlates with extractive foraging but on nonseasonal embedded foods and a specialized diet.

The third hypothesis consists of a phylogenetic localization of intelligent tool use in the animal

kingdom. After analyzing the so far reported cases of tool use, based on the characterization of the required forms of object manipulation, the authors suggested the emergence of intelligent tool use in the common ancestor of cebus monkeys and independently in the common ancestor of great apes and hominids.

Object Manipulation

Despite a number of caveats and critics, Piaget's theory has many strengths to address the origin, nature, ontogeny, and function of animal as well as human knowledge. According to Piaget, the sensorimotor development is characterized by three sequentially developed circular reactions. While the *primary circular reactions* are characterized by repeated actions on the self or on environmental objects that can be assimilated to simple schemes, the *secondary circular reactions* depend on voluntary prehension and involve repeated actions that aim at re-creating contingent effects on the environment. When schemes become mobile and freely combinatory, the differentiation between actions that serve as means – like setting aside an obstacle – and the final actions – like grasping the object – emerges. The transition to the *tertiary circular reactions* occurs when the subject begins to explore new objects through serial application of its familiar schemes, thereby getting interested in the outcome of actions rather than in the actions themselves. These actions do not focus on relations between one's own action and an object but rather towards the relations among objects.

Feeding Ecology

In its essence, the original version of the EFH (but see Parker 2015) proposes an *ecological* account for the emergence of intelligent tool use. Times of low-resource availability forced species to exploit novel food items and prompted various behavioral innovations, such as extractive tool use. In general, behaviors involved in locating, extracting, preparing, distributing, storing, and eating food

items may be considered as adaptations to the temporal and spatial distribution of food sources in a given habitat.

In behavioral ecology, a major distinction is between generalists and specialists, which may be better viewed as ends on a continuum. Dietary generalists, such as cebus monkeys, great apes, and hominids, feed on a variety of seasonally available foods. Such a feeding strategy may involve the extraction from a matrix or a case through intelligent complex object manipulation and means for discovering and remembering their spatial and temporal location. In contrast, dietary specialists, including context-specific tool users, like Galapagos finches or New Caledonian crows, may have evolved sophisticated forms of production and use of tools (e.g., hooked-tool manufacture) in order to gain access to high-quality food sources (e.g., larvae) during most of the time, making up a large portion of their natural diet.

Tool Use

It is not the *fact* that animals use tools that is interesting or significant in itself, but the *manner* in which the tool is employed. In order for tool use to qualify as being “intelligent,” it needs to be flexibly and creatively adjustable to novel situations.

In general, two sets of factors might explain the difference in tool use between two or more species under investigation. Extrinsic factors (i.e., in response to external stimuli) are ecological and social factors, which alone or together can shape the emergence and maintenance of tool use in the wild. Species may also differ intrinsically, in terms of their cognitive ability, their predisposition, or intrinsic motivation for tool use.

A recent collection of reviews (Biro et al. 2013) has shown that in many prominent cases of tool use empirical evidence for extrinsic factors is weak. For instance, a close examination of the habitats and behaviors of bonobos and chimpanzees revealed that the difference in their tool use may be better explained by predispositions rather than social or ecological

opportunities. It is also possible that tool use evolved as a by-product of generalized intelligence evolved in another context.

Taxonomic Distribution

The most recent comprehensive attempt to define and categorize tool use has proposed that associative (or intelligent) tool behavior includes five types of tool use: tool sets, sequential tool use, tool composite, multifunction tools, and secondary tools (Shumaker et al. 2011). Chimpanzees show all five, and capuchin monkeys at least three, possibly also all five, types of associative tool use. This latest survey would support Parker and Gibson's proposal. However, experiments are under way – in the field as well as in the laboratory – to examine carefully what types of associative tool use other nonhuman animals, especially the prime candidates among mammals and birds, show.

Brain Evolution

Reader et al. (2011) have explored the idea of general intelligence with a principal components analysis. It included extractive foraging plus tactical deception, innovation, tool use, and social learning, as well as three lifestyle or socio-ecological measures (diet breadth, percent frugivory, and group size). All five cognitive variables clustered together on the first component, while the three lifestyle measures clustered on a second, independent, component. This suggests that some form of general intelligence (abbreviated as *g* in the literature) might underlie the evolution of the different cognitive measures, supporting a battery of hypotheses regarding the factors driving brain evolution.

Reevaluating the Extractive Foraging Hypothesis

In 2015, Parker reexamined the extractive foraging hypothesis in light of recent behavioral and brain data, new methodologies for quantifying extractive

foraging, and a new phylogeny of primate intelligence. In this paper, Parker questioned the dichotomy between extractive foraging and social intelligence as mutually exclusive hypotheses for the evolution of primate cognition and brain size. Part of the argument is that cognitive abilities in great apes arose not only as an adaptation for extractive foraging through intelligent tool use but also its social transmission. With this extension, the extractive foraging hypothesis became a socio-ecological, rather than a strictly ecological model.

Nevertheless, some challenges and critical issues to the EFH remain:

- It has been criticized that applying the Piagetian framework, which aimed at describing the cognitive development of human infants, may not be appropriate for animals with very different morphologies, ecologies, and life-history traits.
- Not all tool users are extractive foragers, as tools may also be used for different means (e.g., agonistic interactions, physical maintenance, mate attraction). Especially in primates the focus on tool use employed to extract food overlooks the fact that tools are applied in several different contexts as well.
- One of the best opportunities to examine whether feeding ecology can explain differences in the presence of intelligent tool use is the bonobo–chimpanzee comparison. However, recent studies of tool use in the genus *Pan* have not supported the hypothesis that it is a response to resource scarcity.
- Defining intelligent tool use as being associated with extractive foraging and extractive foraging as foraging aided by intelligent tool use is a somewhat circular argument.
- The distinction between *context-specific* and *intelligent* tool use is too rough, as it blurs the distinction between tool sets, sequential tool use, tool composite, multifunction tools, and secondary tools.
- The breath of the EFH is too narrow, having a strong focus upon primate tool use (chimpanzees, in particular). There is complete overlap between the Aves and Mammalia orders in terms of the tool use context, arguing against any special abilities of mammals or primates (Smith and Bentley-Condit 2010).

Even within primates, high levels of intelligence have independently evolved at least four times, with convergent evolution not only in cebus monkeys and great apes but also in baboons and macaques.

- The EFH argues that capuchin monkeys evolved only limited tool use abilities. This statement overlooks a huge body of recent research on capuchins (e.g., Visalberghi et al. 2015) that shows striking similarities in percussive tool use of capuchin monkeys and chimpanzees.
- It is possible that the seemingly qualitative difference of tool use, between primate tool users and all other tool using species, simply reflects differences in length and intensity of observations.

Conclusion

There is a strong correlation between extractive foraging, tool use, and social learning. While this is consistent with the later extension to the EFH, the correlations indicate a general primate intelligence trait (g), supporting many hypotheses regarding the factors driving brain evolution. Neither social nor ecological intelligence seem to be the sole cause of brain evolution but rather may be intrinsically linked in group-living animals.

Parker and Gibson (1977, 1979) have suggested that intelligent tool use has emerged twice in evolution, both in the primate lineage. However, recent work on tool use – together with innovation and insightful object manipulation– in corvids and parrots suggests that we have much to learn from thinking about hominin intelligence in terms of convergent, multiple independent evolutionary events (Lefebvre 2013). To understand the intelligence of *Homo*, the most invasive and opportunistic primate genus, an invasive and opportunistic avian genus like *Corvus* might be as useful as the currently dwindling and geographically limited populations of our closest sister taxa, the great apes.

Extrinsic Mortality

Amanda Wuth¹ and Sandeep Mishra²
¹Department of Psychology, University of Regina, Regina, SK, Canada
²Faculty of Business Administration, University of Regina, Regina, SK, Canada

Synonyms

Environmental harshness; Extrinsic, age-independent environmental mortality; Extrinsic environmental hazards; Extrinsic morbidity-mortality;

Extrinsic risk; Mortality risk; Nonsenescent-related mortality; Perceived social threat.

Definition

Extrinsic mortality is the age-specific risk of death caused by external forces that is equally shared by all members of a population (Quinlan 2007). Extrinsic mortality is determined by nonintrinsic environmental stressors that are not under individual control (e.g., war, nonlethal injuries, violence, and disease; Machluf and Bjorklund 2015). Organisms experiencing high extrinsic mortality are unable to reduce their mortality risk through increasing resource allocation to somatic maintenance, growth, or defense (Ellis et al. 2009; Placek and Quinlan 2012).

Introduction

Extrinsic mortality is commonly conflated with *environmental harshness* – environments producing greater possibility of death or disability (Ellis et al. 2012). Although harsh environments generate greater mortality risks, these risks include both intrinsic mortality – mortality rates influenced by changes in resource allocation – and extrinsic mortality risks (Ellis et al. 2009; Stearns 1992). Extrinsic mortality cannot be controlled by individuals. Intrinsic mortality, by contrast, is controllable through within-individual shifts in resource allocation. Increasing resource allocation for somatic maintenance, growth, or defense, may reduce an organisms' susceptibility to intrinsic mortality (Stearns 1992). High extrinsic mortality, however, tends to more uniformly favor more accelerated life history strategies (Placek and Quinlan 2012; Wells et al. 2017). Since harsh environments also promote the adoption of fast life history strategies (Del Giudice et al. 2015), extrinsic mortality and environmental harshness are often not differentiated (e.g., Ellis et al. 2009, 2012; Machluf and Bjorklund). Lack of differentiation between concepts may also occur because of practical difficulty in distinguishing between intrinsic and extrinsic sources of mortality (Stearns 1992).

Extrinsic Mortality and Life History Strategies

Life history theory postulates that greater sources of death and disability (i.e., high morbidity-mortality) promote accelerated life history strategies that favor immediate survival reproduction over somatic investment and long-term health (Ellis et al. 2009). Specifically, when extrinsic mortality is high, organisms tend to increase energy investments in rapid growth and earlier reproduction and reduce investments in somatic maintenance and defense (Wells et al. 2017). These allocations lead to accelerated aging and shorter lifespans, rapid growth and early maturation, and increased risk-taking (Wells et al. 2017). By contrast, low-extrinsic mortality favors increased somatic investment and delayed reproduction, leading to slower senescence, more gradual growth, delayed maturation, and longer lifespans (Placek and Quinlan 2012; Wells et al. 2017).

Exemplars of extrinsic mortality are evident in animal and human behaviors. For example, when controlling for intrinsic mortality, Chen and Maklakov (2012) found that nematodes (*Caenorhabditis remanei*) adapted to high extrinsic mortality by adopting an accelerated aging and reproduction schedule. Nematodes that experienced high intrinsic mortality lived 20% longer (Chen and Maklakov 2012). Similar effects have been observed in humans, although it appears that humans appear to be sensitive to more than just external mortality. According to Ellis et al. (2009), human reproductive efforts are not only influenced by extrinsic mortality, but also by extrinsic morbidity. Contemporary life history theory more generally refers to *extrinsic morbidity-mortality*, accounting for effects of various sources of death or disability on resource allocations and reproductive efforts (Ellis et al. 2009). In humans, high extrinsic morbidity-mortality is associated with reductions in parental investment, given that in such environments, parental investment is less consequential for offspring survival (Quinlan 2007). For example, increased exposure to famine and warfare are associated with decreased human maternal care, and high levels of pathogen stress decrease both maternal and paternal investment (Quinlan 2007).

Conclusion

Extrinsic mortality – external sources of morbidity and mortality – favors the development of accelerated life histories. Extrinsic mortality tends to be higher in environments characterized by harshness or unpredictability (Ellis et al. 2009). Given that harsh and unpredictable environments often contribute to both extrinsic and intrinsic mortality, it is often difficult to practically distinguish the two types of mortality. Nonetheless, clear sources of extrinsic morbidity-mortality have been observed in both humans and animals, with resultant behavioral consequences (Chen and Maklakov 2012; Quinlan 2007).

Eye Contact with Adults Versus Babies

Chelsea Loeffler
Oakland University, Rochester, MI, USA

Synonyms

[Bonding](#); [Connection](#); [Gaze](#); [Social communication](#)

Definition

The act of looking into another's eyes as a form of nonverbal communication.

Introduction

Various pieces have investigated the importance in eye contact with babies versus that of adults most likely because it is one of the most universally understood forms of communication. The importance of eye contact between adults and children will be discussed and how they differ from each other and then how this impacts humans on an evolutionary scale and what purpose it serves.

Eye Contact in Babies

One of the most impactful connections begins from the moment the mother first makes eye contact with her infant in which there is a biochemical change in the mother's brain and ends with a bond or as some developers call "attunement" (Cogen 2000). This attunement is what creates trust, and the baby is more likely to form a relationship with a mother/caregiver to respond to their needs on a visual level. Eye contact is what mediates a nonverbal transition in humans, it allows them to feel safe and protected but is not a skill that can be learned, it has to be experienced. The best way to understand eye contact with babies is that there is a connection between the two brains, one of the infant and the other of the adult, and the eyes are what provide that link. Evolutionarily speaking, there is an importance with eye contact since the same is true for the infant when they make eye contact with their parent. For example, when the parent smiles, this creates chemicals in the child's brain to heighten alertness which can calm, protect, or reassure them (Klaus et al. 1970). Think of an example of if you have ever watched a child before and they begin crawling by a table and start reaching for something to knock down. Prior to doing this, they will tend to look back at the parent or caregiver as a "check-in" almost to see if what they are doing is permitted or not. Since humans have been reproducing this unspoken form of communication is what helps create bonds and protects the child.

Eye Contact in Adults

Whereas eye contact in babies can be more thought of as a form of bonding, connection, and security as we age, eye contact in adults is a crucial role in communication as an almost synchronizing signal to understanding one another. Eye contact is also a form of feedback which is why people tend to look up at one another to confirm if what they just said is accurate and if the other person agrees with them (Farroni et al. 2002). There is a purpose for eye contact with adults; we are trying to hand the "conversation baton" as it were to initiate the next person to speaking which could explain why eye contact and autism is such a researched subject. Eye contact also is a way of initiating individuals into something as a form of acceptance. This can be seen daily in a classroom when a teacher poses a question to the class and the students who don't know the answer refrain from eye contact as to not be called on.

Conclusion

It is clear that when we are younger, eye contact is much more important as a means of bonding and survival for the infant, whereas, in the adult stage, it is a form of nonverbal communication exhibiting feelings of understanding and acceptance. Eye contact is one of the most understood nonverbal reciprocal forms of communication that we as humans have. This allows for both giving and receiving information so that we can allocate in mutually understood message with other and do so successfully.

Definition

The primary organ by which animals receive light information and the only structure by which image-forming vision is possible.

Introduction

The glint of a predator’s gaze, plumage of a potential mate, or the ominous dark cloud announcing the approach of a violent storm all represent visual signals imperative to an organism’s survival, and all necessitate the use of vision. Across the animal kingdom, the use of eyes to receive light information has undoubtedly contributed to the massive

radiation and diversification, seen in fossilized and extant members of the animal kingdom.

Sight was one of the major sensory innovations to arise during the “Cambrian Explosion” and provided animals with the means to interpret and react to light information, a driving force in the growing divergence of life strategy and corresponding body plan (Plotnick et al. 2010; Parker 1998; Conway-Morris 2003). The evolution of novel eyes coincides with the first observed examples of complicated behavioral strategies such as predation, demonstrating the value of vision as a tool by which early animals’ thrived (Parker 1998; Conway Morris 2000).

Light information is multifaceted and can be interpreted based on intensity, wavelength, or polarization either alone or in combination. As such, there are multitudes of different ways by which animals receive and use this information, leading naturally to a great diversity of light receiving strategies. Herein is described the basics of eyes found throughout the animal kingdom, with a focus on vertebrates (Fig. 1). The text will briefly explore the immense diversity in structure, function, and development of vertebrate eyes as well as the seemingly contradictory deep conservation and similarity. Such captivating mysteries of multiplicity are expected to instill an appreciation of the intricacy and beauty of eyes that induced researchers since the time of Charles Darwin to wonder how it was all possible.

What is An Eye?

The basis of sight is built on the foundation of a capacity for detection of photons by specialized sensory cells: photoreceptors. These cells are chiefly responsible for the transduction of light energy into cellular signals through the action of a group of light sensitive photopigments – the opsins. In order to efficiently capture photons, photoreceptors require membranes with high surface area in which a multitude of opsins are housed. When photons interact with a photoreceptor’s associated opsins, a chain of signals is induced which culminate in electrochemical signals sent to the brain (Wald 1968).

Eye, The**Fig. 1 Anatomy of a vertebrate eye.**

A simplified illustration of the conserved morphological features found in vertebrate eyes

E

Photoreceptors have been recruited to a variety of structures and organs including some that are nonvisual, such as the pineal-complex which is involved in the entrainment of circadian rhythms in vertebrates (Ekstrom and Meissl 2003). Though photoreceptors are most famously associated with eyes, additional photoreceptive structures exist that are not considered eyes such as the “frontal eye” of the cephalochordate, amphioxus (Vopalensky et al. 2012; Lamb et al. 2007). These structures, while able to detect light intensity, are unable to collect sufficient light information to form images, and by our definition are not true eyes. An image is an integration of light information received by the eye from multiple directions into a signal which, when carried to the central nervous system, is interpreted as a dimensional representation of the environment. An eye is an organ capable of producing such an image.

Image formation requires more than a singular photoreceptive cell, it requires a group, and this grouping must be arranged in such a way that directionality can be perceived. By arranging photoreceptors in a cup shape, the amount of light that can be captured is drastically improved (Fig. 2) In being able to capture directional information, detection of such things as texture, shape, and trajectory of movement is possible. The evolution of an eye with these capabilities allowed for animals to pursue higher energy food, provided another means of species recognition, and most importantly allowed for immediate reactions to potential threats (Lamb et al. 2007).

The Diversity of Eyes

Image forming eyes appear in a diverse number of animal phyla including: molluscs, chordates, annelids, and arthropods. We recognize that the eye of a great horned owl is vastly different than that of a house fly – and yet, both are recognized as eyes. Beneath the umbrella of “image forming” visual organs we find a great number of eyes that have evolved in distinct lineages and elaborated in vastly different ways. In order to better understand the forms that exist, eyes are generally categorized by a few major criteria: (1) if the eye is compound or simple and (2) the type of photoreceptors that comprise the light detecting tissue.

The basic components of any eye involve an opening through which light enters, and a photosensory retina which transduces the light energy into an electrochemical signal. Compound eyes differ from simple eyes in that they combine multiple individual units of light collection. The canonical examples of compound eyes can be found in insects in which many single units of photoreception (ommatidia) group into a large mosaic eye. With the exception of some larval stages, all insect eyes are compound. In contrast, a simple eye [or chambered eye, or ‘camera-style’ eye] relies on the action of a single lens which focuses light through a single opening onto a photosensory tissue, known as the retina. Simple eyes with image forming capabilities are found in molluscs, arthropods, and chordates.

Photoreceptors can be separated into one of two major groups based on their morphology

Eye, The, Fig. 2 An eye cup offers the advantage of detecting directionality of light. Over the course of evolution, early photoreceptor structures like the light sensitive eye patch (a) developed first. Relatively simple in organization, the eye-patch is comprised of pigmented photosensory cells which synapse onto ganglion nerve

fibers for the transport of light information to the brain. As discussed, the presence of visual pigments are necessary for the proper photoreceptive function of the photosensory cells. An eye cup (b) improves visual acuity by better allowing the perception of direction (Eakin 1982)

and mechanism of cellular signaling (Eakin 1965). An important feature of photoreceptors is their capacity to hold opsins within their membranes. In ciliary photoreceptors, opsin levels are increased by a corresponding expansion of the membrane surface by the specialization of cilia. Rhabdomic photoreceptors increase membrane surface area by forming microvilli on the cell surface (Eakin 1982, 1965). This dichotomy of ciliary and rhabdomic photoreceptor cell types is defined not only by morphology, but also by intracellular signaling in response to the conformational change to the opsin upon absorbing light. In ciliary photoreceptors intracellular signaling via phosphodiesterase is utilized to hyperpolarize the cell, whereas in rhabdomic photoreceptors depolarization is initiated by phospholipase C (Arendt 2003; Fernald 2000). A large scale appraisal reveals a general pattern, in which invertebrates have typically retained the rhabdomic style, while vertebrates use ciliary photoreceptors, though ciliary and rhabdomic types do co-occur in some instances (Arendt 2003).

The Vertebrate Eye

Vertebrates represent a wide array of body plans, adapted to suit aquatic, terrestrial, nocturnal,

diurnal life histories, among others. Yet, despite this divergence, vertebrate eyes are strikingly similar. All vertebrate eyes follow the same pattern: camera-style simple eyes containing a cornea, lens, and three-layered neural retina and performing vision via ciliary photoreceptors (Fig. 1).

Each eye begins in the same way: as a lateral bulging-out of the anterior portion of the neural tube, an embryonic structure of neural ectoderm origins that will give rise to the central nervous system. These out pockets (optic vesicles) come into contact with epithelial ectodermal tissue overlying the neural tube, which induces invagination of the neural tube to form an optic cup, and the epithelial ectoderm to form the lens placode. From here, the optic cup develops the major sensory tissue of the eye (the retina), while contact with the ectodermal tissue induces the formation of the lens from the lens placode. In this sense, the eye can be considered a direct extension of the brain.

The resulting eye is organized into several layers. Most exterior are the sclera and cornea, involved in providing structural support and protection for the eye, and focusing light onto the retina, respectively. Next is the choroid, which contains a network of vasculature responsible for supplying all other layers with blood, and the

ciliary body, which includes the intraocular muscles as well as the ciliary epithelium which produces the fluid of the aqueous humor, the liquid that fills the space between the cornea and ciliary body. The innermost layer is the three-layered retina comprised of photoreceptors, interneurons (such as bipolar, amacrine, and horizontal cells), and the retinal ganglion cells which together form the optic nerve and are responsible for transferring information to visual processing regions of the brain.

In simple terms, the eye can be imagined as a photoreceptive layer which has, over the course of evolutionary time, elaborated its own structure and organization as well as adopted accessory structures to improve vision. The lens, cornea, and other nonsensory components of the eye all work to improve acuity, efficiency, and longevity of the eyes function. Together, these tissues have become one of the most relied upon sensory structures dictating animal behavior and ultimately success.

Vertebrate Eyes: A Case Study in Evolutionary Innovation

Vertebrate eyes are an incredible example of evolutionary conservation. While invertebrate taxa with image forming eyes such as molluscs have drastically diverse eyes ranging from compound to camera-style, all vertebrates share the same basic eye structure. This high degree of shared similarity provides a unique perspective from which to study eye development as a whole. Since the same eye we see in mammals is seen in even the most basal vertebrate group – lamprey – we know that the vertebrate eye has remained relatively unchanged since its first recorded appearance around 500 million years ago (Dickson and Collard 1979; Morshedien and Fain 2015). This leads to the conclusion that the last common ancestor of lamprey and jawed vertebrates must have possessed some version of the camera-style eye that we see in extant vertebrates. Remarkably, then, the vertebrate eye as we typically consider it arose in evolution prior to the appearance of jaws or paired limbs.

Naturally, curiosity has led to the study of living members of lineages that evolved earlier than vertebrates for clues as to how the vertebrate eye evolved. An obvious candidate for study is hagfish. Like lamprey, hagfish is a jawless fish, but due to the incongruence between molecular and morphological data they have not been included with lamprey as a vertebrate (Lamb et al. 2007). In hagfish, the eyes are comparatively small and lack many of the characters found in vertebrates such as a lens, cornea, or intraocular and extraocular musculature (Lockett and Jorgensen 1998). The eyecup is relatively simple and masked by semitransparent or nontransparent overlying epidermis and a bilayered retina that appears to lack interneurons (Lockett and Jorgenson 1998; Holmberg 1970). This final piece of evidence, the lack of retinal layering like that seen in vertebrates, in addition to projecting the optic nerve to the region of the brain associated with circadian rhythm rather than image processing, is what has led many to categorize the hagfish eye as more pineal-like than eye-like (Lamb 2013). Due to its apparent “primitive” structure in combination with the hagfish’s basal phylogenetic position, it is an attractive idea to hypothesize that the hagfish eye might represent the basal condition of the vertebrate eye before it evolved into the highly conserved structure across extant vertebrates. However, the contentious relationships within cyclostomes remain unresolved which complicates any interpretations we can make from this (Lamb et al. 2007).

The ammocoete (larval stage of the lamprey) provides yet another unique perspective on the history of vertebrate eye evolution. As the ammocoete reaches maturation, it will undergo a drastic metamorphosis in order to reach adulthood. During the larval stage, the eyes of the lamprey are much less developed than that of their adult counterparts. Similar to adult hagfish, the eyes of the ammocoete are relatively small and found beneath a layer of epidermis with a retina that lacks defined layering of the adults (Rubinson 1990). Over the 5 years of maturation that takes place, the cellular differentiation of the retina that occurs follows a nearly identical sequence we see in jawed vertebrate eye during development (Rubinson 1990; Rubinson and Cain 1989).

The crossover between the features of the hagfish and larval lamprey has either been interpreted as lamprey evolving from some ancestral state shared with hagfish, or that possibly hagfish evolved from a lamprey-like state but retained its larval features into adulthood. However, there still remain too many unanswered question for conclusions to be made as the hagfish's position in relation to lamprey is still contested. This underlines the importance of more fully understanding the hagfish in order to better tell the story of how the vertebrate eye evolved.

Conclusion

In vertebrate and invertebrate groups alike, eyes have evolved in a colorful array. The distinct and numerous image forming eyes that exist speak to the great importance that light has played as an invaluable environmental signal in the evolution of animals. The eye has undeniably served as a fundamental driving force in the success and rapid radiation of animal phyla. In vertebrates, the benefit of the eye is most markedly observed in its conservation across the entire subphylum – evolved in some early ancestor and left nearly unchanged through such evolutionary novelties as the jaw and tetrapod limb. As we gain a greater knowledge of living examples of eyes, we can begin to draw more decisive conclusions and better understand the events in the evolutionary history of the eye. In doing so, we draw ever closer to better knowing the eye that developed 500 million years ago and has been serving us nearly unchanged since then.

Definition

Animal color patterns consisting of roughly concentric rings of contrasting colors.

Introduction

Eyespots are animal color patterns consisting of (roughly) circular, often concentric rings of contrasting colors. Eyespots have received their name because (at least to humans) they often resemble the vertebrate eye. Eyespots are common in many terrestrial (land-living) animals such as insects (particularly in larval and adult moths and butterflies), birds and reptiles, but they are also widespread in many aquatic animals such as mollusks, flatworms and fishes (Poulton 1890). Eyespots are highly variable in appearance and occur in a variety of sizes, number and

color combinations. Laboratory studies on butterflies have shown that the processes that explain the development of eyespot patterns are relatively simple and that it requires only one or at least very few changes in the regulatory genes to change the position, color and number of eyespots (Brakefield et al. 1996). This suggests in turn that the evolution of eyespots can occur relatively fast.

Because of their appearance and widespread occurrence in the animal kingdom, the function of eyespots has intrigued naturalists and biologists for more than a century (e.g., Poulton 1890). In some animals, eyespots may play a role in intra-specific (within species) communication or reproductive signaling (Robertson and Monteiro 2005). For example, eyespots of the butterfly *Bicyclus anynana* have proven to be an important signal in mate selection, as females of this species prefer males with larger UV-reflective spots (the center of their eyespots) (Robertson and Monteiro 2005). Another, classic example is the Indian peafowl (*Pavo cristatus*), where the females are attracted to males with more eye spots on the tail. Although these examples show that the eyespots in some species are important in mate choice, eyespots are most well known for their protective function against predators. There are two hypotheses that have been put forward to explain how eyespots in prey protect against predators: (1) *the diversion hypothesis* (also called the *deflection hypothesis*) and (2) *the intimidation hypothesis*.

The Divertive (Deflective) Effect of Eyespots

The common occurrence of (generally small) eyespots found on the wing margins of many moths and butterflies, as well as eyespots located on the caudal area in some species of fishes, has been explained by the divertive function of such eyespots (Poulton 1890; Blest 1957). According to the diversion hypothesis, eyespots serve to direct the strikes of attacking predators toward less vital or defended parts of the prey's body, or toward a direction that would facilitate prey escape (Blest 1957; Kjærnsmo and Merilaita 2013). For example, in a study using yellow buntings (*Emberiza citrinella*) as predators and mealworms (*Tenebrio*

molitor) with a simple spot painted onto them as prey, Blest (1957) argued that the birds directed their attacks toward the eyespots, although firm conclusions could not be drawn as his study was not scientifically sound. However, some empirical evidence for the divertive effect of eyespots has been revealed recently in study systems using passerine birds as predators and butterflies that have marginal eyespots as prey (Olofsson et al. 2010). Olofsson and others showed that the marginal eyespots of the woodland brown butterfly (*Lopinga achine*) drew the attacks of blue tits (*Cyanistes caeruleus*) toward the eyespots, but only under specific light conditions where the UV-intensity of the light was high and the intensity of longer light wavelengths were low (Olofsson et al. 2010). Many species of fish have eyespots located near the area of their caudal fins, and these spots have been shown to misdirect attacks from predatory fish (Kjernsmo and Merilaita 2013; Kjernsmo et al. 2016). The mechanisms behind the divertive effect, at least in the case of fish, may be because the specific shape of eyespots resemble the real eye (eye-mimicry) and confuses the predator (Kjernsmo et al. 2016).

The Intimidating Effect of Eyespots

Another possible antipredator function of eyespots that has been invoked to explain their existence in some prey is predator intimidation (Poulton 1890, Blest 1957). According to the intimidation hypothesis, generally large eyespots (for example, those found in many species of butterflies and moths) could serve to intimidate potential predators, subsequently thwart, delay, or otherwise prevent an attack from being successful. Recent studies have provided support for the intimidating effect of eyespots against passerine birds (Vallin et al. 2005; Stevens et al. 2007; Olofsson et al. 2012; De Bona et al. 2015). However, the question why some eyespots intimidate predators has so far been unresolved and debated. Two main hypotheses for the intimidating nature of eyespots have been proposed. The first is that eyespots resemble the eyes of the predator's own enemy (Poulton 1890; Blest 1957) and hence suggest the presence of a potential threat. The other is that the high conspicuousness of eyespots

is a property that intimidates (Blest 1957; Stevens et al. 2007). Some studies have provided indirect evidence for the idea that predators might associate eyespots with the threat posed by their own enemies. For example, in a study using the domestic fowl as predator and the peacock butterfly (*Aglais io*) as prey showed that when the birds were exposed to butterflies with intact eyespots, they were more vigilant and elicited more alarm calls than those that were exposed to butterflies that had their eyespots painted over (Olofsson et al. 2012).

Conclusion

Even though eyespots in some species are involved in mate choice signaling and intraspecific communication, the existence of eyespots in many prey species can be explained through their protective function against predators. Some, indirect evidence suggests that eye mimicry (the similarity between the eyespot to real eyes) may be an important factor contributing to the extraordinarily wide occurrence of the eyespot pattern.

Definition

Samoan feminine/transgender, same-sex attracted males who are recognized as a “third” gender.

Introduction

In the Samoan language, *fa'afafine* means: “in the manner of a woman.” Like Samoan men, *fa'afafine* are biological males. However, *fa'afafine* do not identify as men nor do the members of their society recognize them as such. Consequently, they have been described as a type of “third” gender that is distinct from both “men” and “women.” In addition, *fa'afafine* differ from Samoan men in that they behave in a feminine manner. From a Western perspective, many *fa'afafine* would be considered effeminate males or transgender. The majority are not transsexual,

however, because they do not experience dysphoria with respect to their genitals. Although it is not unusual for *fa'afafine* to hold certain occupations (e.g., florist) more than others (e.g., mechanic), they have no institutionalized role in Samoa.

Fa'afafine Gender, Sexuality & Social Acceptance

Individuals are recognized in childhood as *fa'afafine* based on their tendencies to engage in female-typical activities (e.g., playing with girls) and their aversion toward male-typical activities (e.g., rough-and-tumble play). This process of recognition does not mean that Samoans make male children into *fa'afafine*. Rather, in Samoan culture, boyhood femininity is interpreted to mean that such individuals simply are *fa'afafine* and it is understood that they will not grow up to be “men.” Some families react negatively to the presence of a *fa'afafine* child with corporal punishment, but the majority have a more laissez-faire attitude, and some even facilitate the child's feminine behavior (Bartlett and Vasey 2006; Vasey and Bartlett 2007).

In adulthood, *fa'afafine* are, almost without exception, exclusively androphilic (i.e., sexually attracted to adult males), and consequently they do not have children (Vasey et al. 2014). *Fa'afafine* do not, however, engage in sexual activity with each other and express disgust at the thought. Instead, they engage in sexual

activity with masculine men. Research indicates that the masculine male sexual partners of *fa'afafine* exhibit bisexual patterns of sexual attraction. Not surprisingly, the majority of these men engage in sexual activity with women, as well as *fa'afafine*.

In Samoa, *fa'afafine* enjoy a high level of social acceptance that, while not absolute, stands in stark contrast to the situation experienced by Western transgender male androphiles. Indeed, *fa'afafine* are highly visible and active members of Samoa society. They occupy all manner of positions from stay-at-home caregivers to Assistant Chief Executive Officers in the government. The Prime Minister of Samoa is the Patron of the National *Fa'afafine* Association and has spoken publically on many occasions about the value of *fa'afafine* for Samoan society.

Conclusion

Owing to their status as feminine/transgender androphilic males, *fa'afafine* exemplify the evolutionarily ancestral form of male androphilia (VanderLaan et al. 2013).

Definition

Recognition is the ability to perceive the physical characteristics of objects (including faces and non-face objects) and categorize these characteristics into classes (e.g., size, shape, color), in order to apply a semantic label to the object (e.g., “coffee cup”) or identify the face (e.g., “Jim from the office”).

Introduction

Human vision evolved to support two distinct mechanisms: recognition of objects and visual guidance of movement. As such, visual processing is instantiated in the brain by way of two

distinct visual pathways that both originate in primary visual cortex (V1) and project to the temporal (ventral stream) or parietal (dorsal stream) cortex (Kravitz et al. 2013). The distinction between these two pathways has been demonstrated in case studies, showing that patients with lesions in the ventral stream nevertheless demonstrate the ability to appropriately reach and grasp objects, despite being completely blind (Goodale et al. 1991). These functionally dissociable neural pathways afford the possibility of using visual information in two fundamentally different ways: the ventral stream for identifying objects and the dorsal stream for guiding action (Kravitz et al. 2013).

Visual recognition is accomplished by integrating both physical properties and spatial information about things in the environment (DiCarlo et al. 2012). That is, objects are generally identified and discriminated based on their size, shape, and color. However, in order to interact with objects, spatial information such as location and position is imperative for visually guided motor actions (e.g., reaching for an object). Humans rely largely on the visual system to perceive and interact with the environment. As humans experience the world, visual information is constantly received by the photoreceptors in the retina of the eye, which is further converted into neural signal and processed through the visual system. The computational burden of this automatic task lies in the fact that while humans may interact with a single object frequently (e.g., coffee cup), the retinal image for that object is *never* the same.

The visual system is comprised of a series of complex mechanisms that have evolved to support survival and reproduction of the species. For example, a highly evolved visual system facilitates such behaviors as navigation or locomotion (Gibson 1966), the ability to quickly detect threat in the environment (e.g., for review, see Green and Phillips 2004), as well as the pursuit and acquisition of resources and mating (e.g., for review, see Motta-Mena and Puts 2017). In the service of rapid valuation and appraisal of the environment, visual perception and attention tend to be adaptively tuned in humans – selectively focusing on the features of the environment that are most important for accomplishing specific goals to

meet the demands placed on the organism (Gibson 1979). In what follows, this entry will review face and object recognition in humans and discuss the contexts in which the perceptual system likely evolved to facilitate survival of the species through rapid detection and valuation of threats and opportunities in the environment.

The Visual Processing System

Anatomically, the ventral visual stream in the brain (colloquially described as the “What” pathway) is a neural pathway comprised of a series of feedforward neural circuits that receive visual input at the retina and innervate through the inferior temporal cortex to facilitate object identification and recognition (DiCarlo et al. 2012; Kravitz et al. 2013). Additionally, the dorsal visual stream in the brain (colloquially described as the “Where” pathway), which projects to the parietal cortex, facilitates the localization of objects in space relative to the perceiver (Kravitz et al. 2013). Together, these functionally specialized and anatomically segregated pathways provide the neural foundation for humans to identify objects in the visual field and provide visual guidance for interaction or motor action (i.e., grasping). The need to identify, recognize, localize, and avoid dangerous objects and predators has likely contributed to the specialization of these highly efficient neural mechanisms found in modern humans (Yovel and Freiwald 2013).

Additionally, there is a network of brain regions in the ventral visual stream that is highly sensitive to biologically relevant information (e.g., faces; Haxby et al. 2000). Humans and nonhuman primates have developed highly sensitive, face-selective cortex to identify and recognize faces vs. nonfaces, arguably due to the critical role that faces play in conveying threat or sociability in the service of species survival (e.g., Green and Phillips 2004).

As one example, the fusiform face area (FFA) is a well-studied brain region that consistently demonstrates pronounced neural selectivity to faces compared to any other type of object (McGugin et al. 2018). Although numerous studies have focused on evaluating the FFA in

humans, the most widely cited model now posits that the neural basis of face processing exists in a *distributed* network of regions in the cortex, including the occipital face area (OFA), superior temporal sulcus (STS), and anterior temporal lobe, all of which serve different, but overlapping, functions (Haxby et al. 2000). For instance, the FFA is sensitive to processing the identity of a face, whereas the OFA and STS are sensitive to facial features and emotion expression, respectively (Tsao and Livingstone 2008). The functional specificity of these brain regions provide context for understanding how environmental demands shaped the evolution and sensitivity of the human visual system to objects and faces.

The Computational Challenge

Objects. The ability to visually detect and recognize objects has clear advantages for survival, as it affords an organism the ability to respond adaptively to different sources of visual information. Survival mechanisms such as avoiding obstacles, detecting dangers and food, and manipulating objects (i.e., tool-making) have afforded modern humans the ability to detect and classify thousands of different types of objects with relative ease and speed (Biederman 1987). However, it is critical to note the computational complexity and biological demand of this seemingly automatic task. The ability to detect, identify, and categorize an individual object that can produce an unlimited amount of different retinal images under varying conditions is at the core of the computational challenge for the visual system. This “invariance challenge” reflects the fact that the visual system must recognize individual objects and faces from various degrees of object positions, scale, illumination, and visual clutter (DiCarlo et al. 2012). For example, visual information for the same object can be ambiguous in different scenarios or contexts (e.g., when an object’s resolution is unclear or partially occluded). This ambiguity must be resolved in order for an organism to respond to, or interact with, the object effectively. Thus, the ability to integrate information beyond the direct visual input at the retina alone was likely adaptive for detecting and identifying threats (e.g., predators), as well as opportunities (e.g.,

food sources), in situations of low acuity or spatial resolution.

The visual system is robust to various perceptual differences in viewpoint, spatial orientation, luminance, occlusion, and acuity of objects in the visual field, something that computer vision has struggled to emulate. It should be noted that from an evolutionary perspective, object recognition in humans may reflect a common mechanism that evolved across various species to solve the problem of visually interfacing with the environment, particularly in the service of navigation. Therefore, despite some differences in gross neuroanatomical organization, many visually oriented animals such as nonhuman primates and pigeons exhibit analogous behavior (e.g., error-driven learning) and neural structures (e.g., basal ganglia) that support visual object recognition in a similarly adaptive way (Soto and Wasserman 2014).

Faces. As in object recognition, face recognition involves a unique set of computational challenges in which an individual must identify and individuate faces under dynamic, varying conditions of illumination, angles, occlusion, and cosmetic changes (e.g., makeup, aging). Additionally, unlike objects, which can provide very heterogenous visual information, all human faces have highly homogenous components such that all human faces look very similar. Therefore, invariant face recognition reflects an even more computationally demanding task than object recognition because the visual system must be highly tuned and sensitive to subtle variations among human faces. Critically, in order to draw accurate and complete social inferences, social behavior fundamentally depends on the ability to form invariant representations of individuals through visual perception in the context of this dynamic, invariant information.

Invariant identification and recognition of faces has been shaped by environmental demands. For example, the organization of social groups into tribes led to unique social demands placed on humans that required accurate identification and recognition of friendly and nonfriendly faces (Parr 2011). As well, in social interactions, the visual system must extract information from the

face in order to determine if a stranger is a friend or enemy in order to engage in the appropriate reciprocal interaction. Humans that were more accurate in categorizing threats from nonthreats (especially when solely based on visual information from a distance) may have been more likely to survive and reproduce. As such, the human visual system has evolved invariant identification and recognition face systems that are robust to variations in luminance, spatial orientation, and cosmetic characteristics such as makeup.

Object Recognition

Historically, faces have been studied the most extensively among all object classes, largely due to their social relevance. However, understanding how recognition for non-face objects is achieved is critical for elucidating the mechanisms supporting visual recognition more broadly. Although the nature of object recognition and how these representations are instantiated in the brain remains hotly debated in the literature, it is unquestionable that humans are highly adept at distinguishing object categories (e.g., cars, places, scenes; Scherf et al. 2007). On the one hand, some researchers contend that object recognition is a unique ability, independent from face recognition (Shakeshaft and Plomin 2015). On the other hand, results from several studies measuring individual differences in perception of non-face objects and faces suggest that recognition for faces overlaps highly with certain non-face objects, such as cars (e.g., Gauthier et al. 2014). While it is yet unclear whether object recognition evolved as a uniquely separate mechanism from face recognition, both processes are highly specialized for supporting survival of the species.

Goal-Directed Behavior Shapes Visual Object Recognition

In Gibson's ecological approach to perception (1979), visual perception is intimately linked with the action systems guiding an organism's behavior. Gibson argued that perception is guided by the possibilities – or *affordances* – that an object provides, such that an object may be

perceived and utilized in different ways given an organism's different goals (Gibson 1979). For instance, a tree branch may be used as a crutch for the injured or as a weapon for self-defense. Importantly, the organism's *perception* of the object physically does not change but rather that the possibilities to act on an object change as a function of the goal of the organism (Gibson 1979). Further, Gibson described the relationship between perception and action as direct, with no sensory processing and without consideration for the organisms' past experiences, present emotional state, or overall social cognition. Gibson's ecological approach to perception is highly functional in nature and provides an understanding of how an organism employs visual perception to interact with its environment.

Applying such theoretical principles to social cognition involves extending the theory to include other intangible aspects of the organism, including mental and emotional states, functionally relevant individual differences, and overall social cognition (McArthur and Baron 1983), in order to understand how such perceiver characteristics may influence visual perception.

Face Recognition

Human faces are pervasive within the visual environment. From birth, humans spend more time looking at other human faces than any other classes of objects. But is this attentional bias uniquely human? The phylogenetic distribution of face recognition shows evidence of convergent evolution for some species that are organized in social groups and that primarily rely on visual information for survival. For example, the ability to recognize the faces of individual conspecifics is evinced in nonhuman primates (for review, Parr 2011) and even paper wasps (Tibbetts et al. 2019). This indicates that some species (including humans) evolved a highly sensitive face processing system for detecting and recognizing conspecific faces to meet selection demands. For primates, sociality was likely driven by the need to minimize predation risk and acquire resources (Gintis 2000). As such, natural selection favored

those primates who were better able to recognize conspecifics in their group. Consequently, increased sociability generated novel fitness demands due to local competition for scarce resources including food and potential mates. Therefore, the face processing system likely evolved to meet two environmental demands: (1) The ability to recognize members of the species to reduce predation risk and (2) recognize individual members within the group for peer and threat identification. This ability to recognize individual faces as friend or enemy presents a unique set of visual demands since most faces have the same or similar configuration. As such, it is through the use of configural information and holistic processing that the human visual system makes faces dissociable and recognizable.

Configural Information

All primate faces have a first-order configuration represented by the canonical inverted triangle shape formed by the spatial arrangement of the eyes, nose, and mouth (Diamond and Carey 1986). As such, modern humans are perceptually attuned to this specific orientation, and this perceptual attunement supports the detection of faces vs. nonfaces. Faces are also categorized based on second-order configural information, which represents the relative spatial arrangement among these facial features including position and spacing (Diamond and Carey 1986). To individuate faces of conspecifics, it is necessary to discriminate and recognize subtle variations in second-order information as all humans have the same basic first-order configural information. Outlined by Bruce and Young (1986), humans first encode the visual perceptual properties or the “structure” of the face to recognize it as another person. Secondly, humans map individual traits to that particular face as a distinct entity. It is through the sensitivity of this configural information that humans are capable of recognizing individuals. By extracting this information from the face, humans are able to recognize friends versus enemies, kin vs. non-kin, and potential mates by making sex-based judgements using sexually dimorphic facial features (Boyer and Bergstrom 2011). In short, humans are

perceptually attuned to perceive faces displaying a highly specific configural orientation.

One of the most common ways to evaluate the use of configural information for face processing is by instructing individuals to detect and remember a face that is rotated 180 degrees (upside down). In humans, inverted faces are detected more slowly and are harder to remember compared to upright faces (Yin 1969). This indicates that humans have likely evolved a specialized neural system to rapidly process a specific type of stimuli: upright faces. If sociability drove the evolution of primate vision, recognition of conspecifics as sources of opportunity or threat almost certainly was unique to upright faces. As such, disrupting the natural configuration of a face disrupts the face-selective neural mechanism for processing the inverted face as a face. Instead, inverted faces are processed like objects using local (or featural) information instead of configural information (Tanaka and Simonyi 2015). Objects tend to be processed on the basis of their individual parts, while faces are processed by the sum of their parts, or holistically (Tanaka and Simonyi 2015), thereby reflecting a core difference in the underlying mechanisms subserving face and non-face object recognition.

Holistic Processing

Unlike objects, it is widely accepted that faces are processed holistically by way of integrating all parts of the face into a unified perceptual whole (for review, see Tanaka and Simonyi 2015). This has been demonstrated in an experimental paradigm referred to as the “part/whole” task, in which participants view images of faces and then must recognize facial features in isolation or in the context of the whole face. Generally, people show a superior recognition advantage for parts when they are presented with the whole face (Tanaka and Simonyi 2015).

Another common method for evaluating holistic processing is by using a composite task in which face stimuli are created by joining two complementary halves of two different faces (Richler and Gauthier 2014). When presented, participants must identify one half of a single composite face while ignoring the other. When

aligned, the composite halves are processed holistically making it slower and harder to identify a single half (usually the top). However, when the halves are misaligned, the holistic representation (among both halves) is disrupted, and the halves can be more easily and quickly identified (Richler and Gauthier 2014). This demonstrates that humans have evolved a holistic processing strategy for perceiving faces, which likely facilitates the use of all face information for individual face recognition. It is evident that humans use configural information and holistic processing to discriminate numerous face identities, generally with high precision. Importantly, however, this ability is developmentally sensitive and is refined over time with age, experience, and other factors.

Development of Visual Recognition

Object Recognition

The building blocks for object recognition are evident early in infancy. Within the first few months after birth, infants can make use of object features such as texture, line junctions, edges, shape, and size to categorize and recognize three-dimensional objects. Additionally, once familiarized, infants can recognize the individual parts of simple compound objects but struggle with recognizing more complex objects such as bicycles or chairs (Jüttner et al. 2006). Increasing evidence shows that, through experience with complex objects and functional brain development of the ventral stream, object recognition reaches adult-like levels in late childhood (Jüttner et al. 2013). As well, complementary evidence from developmental neuroimaging studies also demonstrates that the magnitude of object-selective cortex activation in the ventral stream is comparable across childhood and adults (Scherf et al. 2007). Importantly, however, development of one of the most widely studied objects classes, faces, is protracted and continues well into adulthood.

Face Recognition

The literature on the development of face recognition has primarily addressed two key questions:

(1) What is the initial state of face recognition at birth? and (2) When does the face-processing system mature or reach adult-like levels? Within this framework, some authors have proposed that humans evolved an intrinsic predisposition to process face information (Morton and Johnson 1991) whereas others have suggested that face expertise develops in response to experiencing faces, the most frequently viewed category of stimuli in humans (Nelson 2001).

Morton and Johnson (1991) proposed the CONSPEC/CONLERN theory, which has been one of the most influential developmental theories of face processing. The first aspect, CONSPEC, is a set of subcortical sensory systems that directs infants' attention to face-like information to facilitate the detection of faces. Numerous studies have demonstrated that newborns show natural preferences to face-like compared to non-face stimuli (Morton and Johnson 1991). However, others have shown that newborns also preferentially attend to face-shaped stimuli that have more components in the top half compared to the bottom half (Macchi et al. 2004). Furthermore, evidence from neuroimaging shows that these "top-heavy" visual stimuli activate the FFA in adults (Caldara et al. 2006). In short, there is still much debate about whether early visual preferences for faces is face-specific or reflect general visual preferences. Regardless, these early visual biases to face-like information likely stem from the vital importance for newborns to detect their caregiver or kin through the use of visual information.

The second component, CONLERN, is a face-specific cortical system that develops with exposure to faces and affords infants the ability to individuate faces, allowing face recognition abilities to develop. By 2–3 months of age, infants show increasing preference to the inner configural features of faces, even when compared to "top-heavy" face-like stimuli (Turati et al. 2005). Importantly, these specific face-processing skills, like the use of configural information, are refined with experience and lay the building blocks for adult-level face recognition in adulthood. For example, evidence from neuroimaging studies demonstrate that face-selective areas of cortex

become increasingly specialized as children age (Scherf et al. 2007).

As demands on the visual system continuously change throughout childhood and adulthood, so does the ability to successfully and accurately recognize faces. Specifically, face recognition improves well into adulthood (Hills and Lewis 2018), and the functional development of face-selective cortex have similarly protracted developmental trajectories into adulthood (Scherf et al. 2007). This indicates that while face processing abilities such as the use of configural information and holistic processing develops rapidly in children, the computational demands of face recognition, which reflect the most computationally demanding form of visual recognition, may require more time to develop. In sum, infants have some level of expertise in face-processing including the use of configural information and holistic processing, but these abilities are not adult-like yet, and face recognition abilities continue developing through adolescence and into adulthood.

Conclusion

To conclude, the human visual system is a highly specialized and computationally complex neural system that has evolved to support visual recognition of objects and faces in the service of facilitating survival of the species. Faces and non-face objects provide a wealth of information that must be rapidly processed by the visual system for rapid categorization and processing of the stimulus (including a face's age, sex, and race, or an object's color, shape, and size). Despite the vast computational challenge this presents for humans, these abilities are supported by neural architecture that underlie the rapid integration of both physical properties and spatial information about a stimulus (DiCarlo et al. 2012). For faces, this rapid integration of information is instantiated through the use of configural information and holistic processing allowing rapid and accurate discrimination of individual people, which is present in infancy. However, these abilities develop through childhood and adolescence, and in the case of face recognition, into adulthood. Ultimately, the ability

to identify and recognize numerous objects and faces is a highly evolved ability that is arguably refined with experience. While object and face recognition in typically developing humans is well studied, future research would benefit from evaluating populations with neurological disorders and/or impairments in visual processing. As an example, some of the most compelling evidence in favor or against certain theoretical models of face processing have been informed by patients with lesions to the ventral visual stream, or prosopagnosia (i.e., face "blindness"). As well, neurodevelopmental disorders such as autism, which is characterized by deficits in face but not object recognition, can provide insight into the distinctiveness and plasticity of these neural systems and theoretical models.

Definition

Face recall is the cognitive ability to retrieve previously stored face information without visual input of the stimulus.

Introduction

The visual system in modern humans is marked by a number of cognitive specializations that have been shaped by evolution. One such specialization is the ability to rapidly extract, store, and retrieve visual information from the face. For example, humans can store and freely recall up to 1000 face identities without explicit training or effort (Jenkins et al. 2018). Furthermore, humans can recognize nearly four times the number of face identities that they can recall (Jenkins et al. 2018). These two abilities – *face recall* and *face recognition* – are distinct cognitive processes that involve different levels of perceptual input, engage unique but overlapping neural mechanisms, and were likely shaped by different environmental demands. This entry will focus specifically on what makes face recall a particularly unique cognitive ability among the various mechanisms supporting face processing behavior.

Recall Versus Recognition

Face recognition is the ability to discriminate faces from nonfaces and recognize familiar and unfamiliar conspecifics (and heterospecifics) based on information retrieved from visually perceiving a face. In contrast, *face recall* is the cognitive ability to retrieve previously stored face information *without* a need for visual input of the stimulus. This means that to recall a face (relative to recognizing a face), the brain must actively generate the neural representation of the intended face and determine if it is the “correct” one (Yonelinas 2002). To illustrate, the dual-process theory would suggest that face recall begins by “replaying” the pattern of neural activity that was originally generated when the face was perceived and encoded (Yonelinas 2002). The

reason this is a challenging task is because the brain must first reconstruct the information by engaging the pattern of neuronal activation involved in the memory and then determine if the generated memory is the correct one (e.g., for review, see Yonelinas 2002). This subtle difference in perceptual input (e.g., whether a face is visually present) is what makes face recall distinct from face recognition; recall requires the active generation and retrieval of a face identity, whereas recognition requires a familiarity judgment of the face that is currently viewed.

In modern psychology, face recall is commonly evaluated through the use of memory paradigms utilizing famous faces as the stimuli of interest (Russell et al. 2009). These paradigms involve participants viewing images of famous faces and subsequently recalling the faces they saw without the images or contextual cues presented. The reason famous or familiar faces are used is that there is a tightly linked semantic label that participants can verbally associate with the image (e.g., Lady Gaga, Brad Pitt) and subsequently recall when prompted. Without this semantic association, it becomes difficult to quantify the ability to recall faces as participants would simply describe various features of the faces that they remember without a clearly associated verbal label or identity for the face. Behaviorally, humans can only recall 25% as many faces as they can recognize (Jenkins et al. 2018). This asymmetry suggests that face recall and recognition are distinct processes with different levels of cognitive demand.

Face and Memory Neural Systems

Episodic memories are personally relevant experiences or episodes, like viewing a face, that are stored in long-term memory (Renoult et al. 2016). Therefore, the ability to retrieve face identities from long-term memory fundamentally depends on the core neural substrates of episodic memory, which include the medial temporal lobe (MTL; Aggleton and Brown 1999). In particular, the role of the hippocampus in episodic memory formation and retrieval is nearly ubiquitous for not only

faces but nearly every type of stimulus (Bird 2017). Given the strong role of the hippocampus in recalling past experiences, there has been extensive debate as to whether recognition memory is also hippocampal-dependent or if recognition is accomplished through familiarity processing in the ventral visual stream and extra-hippocampal areas (e.g., Montaldi and Mayes 2010). However, when considering face stimuli, there is overwhelming evidence of intact visual recognition in hippocampal-lesioned nonhuman primates and humans who sustained hippocampal damage (see Bird 2017). This indicates that the hippocampus may be required for face recall, but not necessarily recognition.

Face recall and face recognition are at least partially instantiated in the brain as distinct mechanisms. On one hand, face recognition is primarily supported by the core face processing network (Gobbini and Haxby 2007). On the other hand, face recall is supported by the “core” face processing network *and* the episodic memory system, which are instantiated in the ventral visual stream and the medial temporal lobe (MTL) of the brain, respectively (Gobbini and Haxby 2007; Squire et al. 2004). These neural systems are anatomically and functionally distinct, but converging neuroanatomical evidence suggests that the ventral visual stream has substantial anatomical projections directly to the MTL, including perirhinal cortex, entorhinal cortex, and the hippocampus (Suzuki and Amaral 1994). Importantly, these neural regions, especially the hippocampus, support long-term memory storage and retrieval, highlighting the fact that the face processing network has direct neural connections with the core nuclei for episodic memory, and reflecting the importance of encoding visual information into long-term memory. As a consequence, the ability for humans to recall as many as 1000 faces fundamentally depends on the neural structures that support memory.

Face Recall Facilitates Group Cohesion

The visual system in modern humans facilitates species survival through a variety of mechanisms,

including rapid detection and valuation of threats, and opportunities in the environment (e.g., Griffin and Motta-Mena 2019). In particular, the ability to identify and respond to *facial* information would have been evolutionarily adaptive for such behaviors as threat detection, resource acquisition, and development of social networks. In fact, humans have developed complex cognitive face processing mechanisms to recognize faces but also support the storage and retrieval of hundreds of face identities (Gobbini and Haxby 2007). In what follows, we describe the potential adaptive value of face recall and how it may have differed from face recognition.

Face recognition is a crucial adaptation that facilitates immediate detection of threatening and non-threatening conspecifics and heterospecifics in social species. This is evinced phylogenetically in a number of species including nonhuman primates, paper wasps, canines, and sheep (Calder et al. 2011). Consequently, the extent to which face recognition is a shared evolutionary ability across primates has been extensively reviewed (Griffin 2019; Parr 2011). In contrast, the degree to which face recall is a cognitive and behavioral adaptation that emerged through evolutionary pressures may be rooted in sociality of the primate species. Humans maintain social networks of around 100–200 individuals, and 60% of communication is related to gossip or past experiences (Dunbar 1993). Relatedly, storytelling is universal in humans, and its adaptive value is demonstrated in coordinating group behavior, facilitating social cooperation, and establishing social norms of the group (Smith et al. 2017). For example, sharing experiences or stories about previous conflicts promotes cooperation among group members since it teaches group members about the payoffs of cooperation and sets expectations for how the group will behave (Smith et al. 2017). The social communication and transmission of these expectations and social norms from generation to generation are the cornerstone of cultural knowledge and information preservation across generations. Importantly, face recall supports the ability to share experiences and stories about other *people* because individuals are most rapidly individuated by their

face. Therefore, throughout evolutionary history, face recall likely facilitated increased sociality among individuals, which is related to larger group sizes, reduced predation, and access to resources (Chapman and Teichroeb 2012).

Conclusion

Face recall and face recognition differ in the amount of visual input, neural processing, and evolutionary adaptiveness. For example, face recognition is the ability to recognize a currently viewed face as familiar or not, whereas face recall is the ability to recall the face identity without currently viewing the face. Although both abilities are supported by neural structures serving the face processing system, face recall is additionally dependent on the episodic memory system, especially the hippocampus. Face recall may have adaptive value in the sharing of past experiences with other group members, which increases social cohesion, whereas face recognition serves to rapidly evaluate immediate threats in the environment based on visual input. Face recall may be a recent evolutionary adaptation that strengthened social networks, increased group size, and ultimately, survival and evolution of modern human cognitive abilities.

[Face preferences](#); [Facial aesthetics](#); [Facial beauty](#)

Definition

Attractive faces are faces that are liked and preferred over less attractive faces. Attractiveness is often measured using rating scales in which faces are rated on a scale of attractiveness (e.g., 1 = low attractiveness and 7 = high attractiveness) or using two alternative forced choice decisions (e.g., which face is more attractive face A or face B?). Facial attractiveness concerns the traits

that make individual faces more or less attractive as well as the mechanisms via which facial attractiveness is appraised.

Introduction

Our physical appearance is the first thing that people can observe about us and the human face is one of our most prominent physical features. People are very interested in the faces of other people and consequently faces dominate our art and media. The reason for this interest is that our faces play an especially important role in our social lives. Faces are the focus of our attention because of the information we glean from them: we can see a person's sex and age, tell what they are attending to, and guess their feelings and emotions from their face. It is then unsurprising that humans have extraordinarily well-developed abilities to process, recognize, and draw information from others' faces. Humans also appreciate attractive faces, and evolutionary approaches have shed light both on what features make a face beautiful and the reasons behind why we might find such traits attractive.

If you were to describe a beautiful face you might find that the qualities that make it attractive over other faces are difficult to articulate. Despite this difficulty in accessing the causes of our preferences, we assess facial beauty quickly and there appears to be agreement within a particular culture and also between individuals from different cultures (see Langlois et al. 2000 for a meta-analytic review). This agreement on which faces are attractive and which faces are not attractive suggests that people are all using the same, or at least similar, criteria in their judgments. Even infants at 3–6 months prefer to look at faces which are rated more highly for attractiveness by adults than at faces rated lower (Samuels et al. 1994). It therefore appears that before any substantial exposure to cultural standards of attractiveness infants demonstrated a preference for attractive faces that are in agreement with adult judgments. Both early developmental and cross-cultural agreement on attractiveness are evidence that suggest that attractiveness ideals are not slowly absorbed by

those growing up within a particular culture and that there is something universal about attractive faces (and unattractive faces) that is recognized both across individuals and cultures, in adults and in infancy.

An Evolutionary Approach

So, why are some faces preferred over others? Evolutionary theory may cast light on what features are attractive and why attractiveness is important to us. An evolutionary view suggests that preferences should serve an adaptive function: preferences drive us to acquire high quality mates and the traits that we find attractive in individuals may be directly linked to their value as mates (Symons 1987). High quality/value mates are those who can best enhance the reproductive success of the judge. Women and men should both be sensitive to cues that indicate higher mate value because individuals who were attentive to cues of high mate value, and based mate-choice decisions on them, left behind more offspring, which would be healthier and more fecund, than those who failed to attend to these cues.

There are two main types of benefit that may be associated with mate quality that involve benefits to the chooser. These are indirect benefits, usually genetic benefits that are passed onto offspring such as genes associated with strong immune function, and direct benefits, reflecting a wide range of factors that directly benefit the chooser such as access to resources and territory, high quality parental care, and lower chances of contagion from healthy individuals. While the distinction may be important, it is difficult to disentangle the two benefits. For example, choosing a healthy partner may lead to offspring inheriting genes resistant to disease but avoiding a parasitized mate also has obvious direct advantages whether parasite resistance is heritable or not.

In support of this evolutionary view, there is evidence of potential benefits associated with mating and reproducing with an attractive partner. Individuals who partner with attractive faced

people may then produce more children and have a long-lived partner to provide parental care for their offspring. If these traits are heritable, then those who select attractive faced partners may also produce offspring who are attractive, long-lived, and who will themselves produce more children.

Attractive Face Traits

As noted already, describing the traits associated with attractiveness is difficult. Faces vary in many different ways and many of these variations impact on the judgment of attractiveness. Research has highlighted a large number of facial traits that impact on attractiveness and a comprehensive review is beyond the scope of this entry. In terms of what people on average find attractive, younger appearing faces are more attractive than older faces, healthy appearing faces are more attractive than unhealthy faces, average faces are more attractive than less average/more distinctive faces, and symmetric faces are more attractive than asymmetric faces (see Little et al. 2011 for review). There are potential benefits associated with choosing individuals based on each of these traits and so directional preferences can be predicted. For example, youth is associated with a longer period of potential parental investment and, at least in women, youth is strongly associated with the ability to produce offspring over time. Choosing a healthy partner has obvious adaptive benefits both in terms of direct and indirect benefits, and the traits of averageness and symmetry have both been linked to health: average faces may be attractive because the owners of average faces possess a diverse set of genes which may lead to better resistance to common pathogens while symmetry may be a marker for developmental stability (see Little et al. 2011 for review).

Masculinity, Femininity, and Attractiveness

The relative masculinity and femininity of a face has also been linked to attraction in many

studies. Larger jawbones, more prominent cheekbones, and thinner cheeks are all features of male faces that differentiate them from female faces. There is considerable evidence that feminine female faces are considered attractive. Studies measuring facial features from photographs of women (Grammer and Thornhill 1994) and studies manipulating facial composites (Perrett et al. 1998) all indicate that feminine features increase the attractiveness of female faces across different cultures. The link between sexual dimorphism and attractiveness in male faces is less clear. Studies using facial measurements have found that females preferred large jaws in males, but several studies have also shown that feminine characteristics and faces of low dominance are of increased attractiveness (see Little et al. 2011 for review). Studies manipulating masculinity and femininity in faces also produce mixed results: several studies have documented preferences for femininity but similar computer graphic studies have also reported preferences for masculinity (see Little et al. 2011 for review).

One explanation for the variety in findings to do with masculine versus feminine preferences for male faces may lie in the personality traits masculine and feminine faced males are assumed to possess. Increasing the masculinity of face shape increased perceptions of dominance, masculinity, and age but decreased perceptions of warmth, emotionality, honesty, cooperativeness, and quality as a parent (Perrett et al. 1998). It appears that socially valued traits such as honesty, warmth, cooperation, and skill as a parent are associated with feminized versions of male faces, while traits such as dominance are associated with masculinized face shapes. Feminization of male face shape may increase attractiveness because it “softens” particular features that are perceived to be associated with negative personality traits. Female face preferences may thus represent a trade-off between the desire for good-genes, or other benefits, and the desire for a cooperative partner. This trade-off means that masculinity in male faces may be more or less attractive under certain contexts and to certain individuals generating variation.

Variation in Perceived Attractiveness

Despite broad agreement on attractiveness, there are many other factors that may influence an individual in determining who they find attractive. In fact, in a truly adaptive view of preferences we might expect that individuals would vary in their preferences according to their personal circumstances and environment. Again, a comprehensive review is beyond the scope of this entry, but research has highlighted a number of factors related to variation in preferences. There are potential within-person differences. For example, women judging men for short-term relationships prefer more masculinity in faces than those judging for long-term relationships (Little et al. 2002). While masculine faces are seen as dominant, feminine faces are seen as making good fathers (Perrett et al. 1998), which means the difference in long-term versus short-term preferences is consistent with the hypothesis that while masculinity may be an important trait for short-term choice, for long-term relationships where investment is an issue, women may change their priorities and look for cues to long-term investment that are not necessarily consistent with traits that indicate high genetic quality or dominance. There are also potential cross-cultural differences. For example, in an environment with high pathogen-risk, the risk of contagion is higher and the probability of offspring survival and eventual reproduction decreases and so individuals under such conditions may favor traits associated with healthy partner. There is some evidence to support this view, with stronger preferences for male masculinity in Jamaicans than in the UK and Japan (Penton-Voak et al. 2004), stronger preferences for facial symmetry in a tribe of African hunter gathers than in the UK (Little et al. 2007), and in a larger cross-cultural sample of 30 countries, stronger preferences for male masculinity in countries with poorer health, such as higher mortality and incidence of disease (DeBruine et al. 2010).

Conclusion

In conclusion, attraction and mate choice are critical components of evolutionary selection, which

can help us understand the importance of facial beauty. There are many face traits that are associated with facial attractiveness in humans, and each may indicate direct and/or indirect benefits to individuals who act on these preferences. If some traits are reliably associated with some benefit to the perceiver, then we can expect directional preferences for particular traits and, on average, there will be preferences for those traits. People tend to agree that traits such as age, health, symmetry, and averageness are attractive in faces. While some traits will be attractive across individuals this does not preclude interesting variation both across individuals and across cultures. Overall, the determinants of facial attractiveness are complex, and an evolutionary approach can help us explain both why we agree on the attractiveness of some faces and also why beauty is, at least partly, in the eye of the beholder.

Synonyms

[Attraction](#); [Avoidance](#); [Disease avoidance](#); [Stigma](#)

Definition

A distortion or a perceived abnormality, as a result of a medical condition or accident that has taken place during the individual's life.

Introduction

Facial disfigurements such as psoriasis, cleft lip, or asymmetry due to congenital or acquired causes are subject to a wide range of stigmatization. Individuals with facial disfigurement have reported being avoided by others when forming and maintaining interpersonal relationships (Clarke 1999) and receive discriminatory treatment in a wide range of settings, such as in education, employment, and healthcare (Lanigan and Cotterill 1989). Such strong avoidance of individuals with facial disfigurement can be attributed to the fact that the face plays an important role in social interaction and is particularly salient for inferring a rapid number of evaluations when making initial contact with someone. Two of the most important evaluations are based on whether they should be approached (i.e., do they appear to be in good health) and whether they appear to be attractive and could make a good partner. These two evaluations correspond with the two most important aspects of evolution, survival and reproductive fitness, respectively. Because of this, the rest of this article will discuss the role of disease avoidance and facial disfigurement as well as the role of attractiveness and facial disfigurement from an evolutionary perspective.

Facial Disfigurement and Disease Avoidance

Disgust is an emotion that is designed to keep us away from disease threats. It is a key component of the disease avoidance system that is designed to detect and avoid disease threat before it makes contact (e.g., the Behavioural Immune System; for a review, see Murray and Schaller 2016). Activation of disease avoidance includes trigger-specific negative emotions such as disgust and anxiety, cognitions such as negative attitudes, and behavioral avoidance. As the majority of pathogens and parasites that cause disease are difficult or impossible to see, animals, including humans, have evolved mechanisms that respond to perceptual cues that infer disease threat. As perceptual cues do not always mean that a disease threat is present, this can lead to inference errors. In simple terms, this means that there is the possibility that a disease threat may be present and could be missed (false negative error) or that a disease threat is not present and avoidance strategies are activated (false positive error). Given the potential high costs associated with missing disease threat and becoming ill, the disease avoidance system has evolved to be overly inclusive and avoid those people who have a cue that could be associated with disease threat where no disease threat is present (Park et al. 2003) and motivates stigmatization (Kurzban and Leary 2001). Furthermore, activation of disease avoidance mechanisms is functionally flexible, meaning that levels of activation are context-specific (e.g., heightened activation if an individual believes themselves to be particularly vulnerable to disease).

As well as disfigurements causing the activation of an overinclusive disease avoidance system, the face itself has been historically associated with providing cues for a wide range of diseases. Sixteen of the 25 diseases that have been found to currently and historically produce the highest rates of mortality and morbidity show signs of visible facial lesions (Wolfe et al. 2007). Despite the link between facial lesions and some of the most harmful diseases, there are many facial lesions that are not associated with infectious disease. For example, a birthmark or a disfigurement

such as a cleft palate would not be considered as a source of disease threat or have the potential to contaminate others. Despite this obvious inference, evidence has demonstrated that these non-disease salient facial disfigurements have the propensity to activate disease avoidant strategies.

Ryan et al. (2012) conducted a study to see whether avoidance behaviors could be associated to seeing facial disfigurements that are not considered as contagious. Participants watched one of three clips that showed actors interacting with objects. One actor appeared healthy, one had a port wine stain birthmark, and one had influenza-like symptoms. Participants were observed interacting with the props in the video and their behaviors recorded. Participants in the birthmark condition showed the same avoidant behaviors (e.g., disgusted expressions, wiping the prop) as were observed in the influenza-like condition. Despite these similar behaviors for the two conditions, participants reported that influenza was far more contagious and lethal than a birthmark. These results show that despite participants being aware that birthmarks are not contagious, disease avoidant behaviors were still activated. Furthermore, it demonstrates how behaviors are not always rooted in rational and conscious motivations. Instead, these disease avoidant behaviors are based on an evolved mechanism that is activated when we are unaware of it and tasked with the sole responsibility of maximizing survival.

Facial Disfigurement and Attraction

Attractiveness serves as the feature that can lead to motivating romantic relationships and ultimately mating. The evolutionary perspective suggests that those features that are considered as attractive are markers that provide indications of health. If an individual does appear healthy, it can be inferred that they will have healthy genes and these will increase the chances of healthy offspring and their subsequent survival.

Fink and Penton-Voak (2002) proposed three features that were associated with the evolutionary perspectives of facial attractiveness. These are

symmetry, averageness, and nonaverage dimorphic features. Symmetry refers to how symmetrical the face would suggest a high quality of development and therefore a high quality of genetic health. The averageness of some facial features could be associated with heritable traits and are therefore preferred. Indeed, computer-generated averaged faces are almost always preferred when compared to the individual faces that were used to make up the averaged ones (Fink and Penton-Voak 2002). Sexual dimorphic traits are associated with masculine features that come from higher levels of testosterone production to encourage mating and competing for mates. When considering individuals with facial disfigurement, they are likely to fail in two out of the three categories that have been described. Any form of disfigurement will have an effect on the overall symmetry of the face and may cue concerns towards the genetic health of the individual. Those with facial disfigurement are also likely to have facial features that are not normally observed in the general population. Again, this may cue a lack of genetic health.

Despite the suggestion that facial disfigurement would be associated with decreased levels of attractiveness and genetic fitness, there is evidence that demonstrates the opposite. A study by Burriss et al. (2009) found that women preferred men with facial scars for short-term relationships, but the same effect was not found for men. For long-term relationships, both men and women showed equal preference for people with or without scarring. Those males with scarring could be preferred for short-term relationships as they appear both masculine and like heroic risk takers. This explanation supports the importance of sexual dimorphism and may be a cue for mate quality (Fink and Penton-Voak 2002). This is further supported by the fact that the preference was only found with females. A further explanation could be that scars demonstrate that the individual has been through a trauma and has survived it. This would suggest that they are a “tried and tested” person with good genetic fitness, instead of someone who can only be predicted as having good genetic fitness.

Conclusion

Due to the historical prevalence of facial cues inferring disease threat and an overinclusive disease avoidance system, this does provide an explanation for why people with disfigurements receive discriminatory treatment and are stigmatized in a wide range of settings. The relationship between attractiveness and facial disfigurement show how features can be used as cues for the genetic health of an individual. However, the picture is far from clear. On the one hand, facial disfigurements can show decreased attractiveness, whereas facial scars on men can actually increase attractiveness by being associated with masculinity. It is possible that rather than an overinclusive response to facial disfigurement and attractiveness, the finer details, such as the inferences, play an important role.

It is important to remember that many of the mechanisms described come from innate mechanisms that are activated at an unconscious level. However, as sentient beings, we have the ability to accept or reject these aversive attitudes or behaviors at a conscious level and we are ultimately still responsible for our own actions.

Definition

Psychologists' interest in facial expressions arose from the long-standing belief that, just as our

dreams were Freud's royal road to the unconscious, our smiles, frowns, pouts, grimaces, and other faces are the royal road to our emotions. The phrase "facial expression" is a presupposition that some event inside, typically an emotion, is pushed outside for public consumption. To avoid any such presupposition, *facial behavior* is used here to describe the movements and positioning of the facial muscles. Likewise, *emitter* and *observer* are used to avoid implying that any "content" is necessarily transferred by the face.

Introduction

Human facial behavior results from a set of roughly 20 muscles. Except for the masseter, which clenches the jaw, these muscles originate on the bones of the face but insert in the skin, where they act as tractors, dilators, or sphincters that modify the orifices formed by the eyes, nose, and mouth. Although the nature of "facial expressions" was discussed for centuries, Darwin's noncommunicative formulation remains foundational.

A Brief History

Historical accounts of research on facial behavior usually begin with Charles Darwin's (1872) *The Expression of the Emotions in Man and Animals*, but his work on *Expression* was a reaction to writings a half-century earlier by physician-artist Charles Bell. Bell had written and illustrated a volume on facial behavior in which he endorsed the prevailing natural theology and regarded the human facial musculature as divinely gifted solely to humans to express emotions.

Bell's depictions themselves drew upon prescientific theorists like Aristotle, who declared that certain faces expressed the "passions and their contraries." Descartes elaborated upon Aristotle's system and listed six primary passions – wonder, love, hatred, desire, joy, and sadness. The Cartesian passions were adopted by Charles Le Brun, court painter to Louis XIV, who prescribed exactly how each should be "expressed" on the face in paintings, drawings, and sculptures. The

French neurologist Duchenne, best known for his “faradism” (electrical stimulation of muscles and nerves), argued from faradic studies that 60 different emotions could appear on the face.

Darwin (1872), intent on discrediting special creation, sought to overturn Bell’s creationist account. As he confided in an 1867 letter to Alfred Russel Wallace, “I want, anyhow, to upset Sir C. Bell’s view . . . that certain muscles have been given to man solely that he may reveal to other men his feelings” (Fridlund 1992). In *Expression*, Darwin rebutted Bell’s twin claims of human uniqueness and special communicative function, first noting how human “expressive” behaviors resembled those of other species and then highlighting numerous noncommunicative features of those behaviors. To that end, Darwin explained most “expressions” using his *Principle of Serviceable Associated Habits*, by which he meant “habits associated with actions once serviceable ancestrally” but which survived only in degenerate form, like webbed feet on land birds, male breasts, and the human appendix. Darwin’s contention that much of our “expressive” behavior is similarly vestigial was decisive for biological evolution: functional movements or structures could be either God’s handiwork or evolution’s, but nonfunctional vestiges could not. Thus, our ancestors might have bared their teeth before kill-biting an interloper, but now we merely bare our teeth without progression to biting. This rudimentary habit no longer accomplishes anything; any signal value is incidental.

Basic Emotion Theories

In the first half of the twentieth century, psychological research found no clear mapping of faces to emotions but instead suggested that (1) observers used contextual information (e.g., what led to making the face) to attribute emotion to the face, (2) facial behavior was better interpreted in terms of broad dimensions (e.g., pleasantness and intensity) rather than discrete emotions, and (3) the interpretations of faces varied somewhat with culture.

Much of this information was eclipsed in the 1960s with the advent of *Basic Emotion Theories*, a set of related frameworks which began with the

writings of personality theorist Silvan Tomkins (for history and critique, see Leys 2017). Tomkins took the received wisdom from Descartes and Le Brun that much of our facial behavior was eruptive and nonintentional, consistent with Darwin’s view, but he also argued *contra* Darwin that these movements arose via natural selection. Faces revealed precisely nine specific, biological “primary affects”: interest, enjoyment, surprise, distress, anger, fear, shame, disgust, and contempt. These affects were categorical, and the faces they produced were iconic. Tomkins’ theory gained traction with the 1960s–1970s research of two proteges, Carroll Izard and Paul Ekman.

Most prominent was Ekman’s *neurocultural theory* with its clear enunciation of the *universality thesis*, which contended that (1) certain “facial expressions of emotion” revealed a small number of categorical “basic emotions;” (2) each expression resulted from a modular emotion “program” in the brain which was triggered by a constrained set of elicitors; (3) these expressions were phylogenetic and, as such, would be produced uniformly, recognized by humans panculturally, and found early in child development and among nonhuman primates; and (4) deviations from uniformity were due to supervention by cultural *display rules* reflecting learned conventions or modes of dissimulation (Ekman, in Fernández-Dols and Russell 2017).

One clear accomplishment of the basic emotion approach was the late 1970s dissemination of an anatomically based system for scoring facial movements (updated by Ekman et al. 2002) developed originally by the Swedish anatomist Carl-Herman Hjortsjö (1969). The basic emotion approach continues to develop conceptually and methodologically and is the basis for much “emotion recognition” software (Keltner and Cordaro, in Fernández-Dols and Russell 2017).

Contrary Evidence

Ekman’s “neurocultural theory” achieved fame with a series of cross-cultural matching (“recognition”) studies, some also conducted by Izard. In these studies, individuals in diverse cultures –

including some small-scale societies in Papua New Guinea and Borneo reputed to have been minimally Westernized – were able to match photos of posed Caucasian faces to indigenous emotion terms at rates greater than chance. The simplicity of forced-choice matching procedures led to their widespread adoption (reviewed by Gendron and Crivelli, in Fernández-Dols and Russell 2017).

The cross-cultural studies were controversial from the beginning especially among field anthropologists who argued that the (1) posed photos were ecologically dubious caricatures, (2) designated categorical “emotion” terms did not capture the diversity of emotion concepts across cultures, (3) investigators underestimated the participants’ degree of contact with the West, (4) matching procedure did not capture participants’ spontaneous interpretations of the faces, and (5) translators may have helped the participants choose the expected responses in cultures that emphasized cooperation (Russell, in Fernández-Dols and Russell 2017).

Subsequent research ratified these doubts. Findings from the first half of the twentieth century on contextual influence, dimensionality, and cultural diversity were all replicated. Agnostic, bottom-up psychophysical methods showed that European and Chinese students differed in their mental representations of faces for specific emotions (Jack and Schyns 2017). Observers matched faces to predicted emotion labels better when the posers were from the same culture. Evidence from African and Melanesian societies, using more sophisticated and diverse research designs, did not replicate the Ekman studies (reviewed by Gendron and Crivelli, in Fernández-Dols and Russell 2017). Trobrianders in Papua New Guinea understood the putative “fear expression” as an agonistic display instead (Crivelli et al. 2016). When the Himba group in Namibia sorted into piles a series of posed faces, they did not recreate the classic “expressions of basic emotions” when the sorting was unconstrained but did so only when emotion concept words anchored the piles at the outset (Gendron et al. 2014).

The matching studies were attempts to test how people understood facial “expressions,” but not

what produced them. Even if people everywhere see happiness in a smile, much as they hear it in birdsong, the question remains whether happiness actually produces the smile (or the song). Contrary to basic emotion predictions, smiling was found to depend more on the presence of an audience than on the emitter’s emotions. In such studies of *audience effects*, people smiled (1) during films only when with friends or believed they were; (2) when bowling strikes, mainly after pivoting to see their fellow bowlers; and (3) after winning Olympic gold medals but only when looking at the audience. One study of the putative “surprise expression” had participants enter a laboratory by a corridor, then leave by the same door only to find a room with posters, bold green walls, and a red office chair. Participants reported great surprise and believed that their faces showed it, but only 3 of 60 made the “surprise expression” expected by basic emotion theorists (Schützwohl and Reisenzein 2012). Overall, production studies like these have shown weak relations between emotion and the predicted facial behavior (Duran et al., in Fernández-Dols and Russell 2017), with one exception: reports of feeling amused correlate strongly with smiling and laughing.

Theoretical critiques of basic emotion theory also emerged: (1) the claim that certain emotions were “basic” lacked foundation (Ortony and Turner 1990), partly because of difficulties with the emotion concept itself, and (2) greater knowledge of biology-culture interactions proved inconsistent with its dual presumptions that “universality” implied phylogenesis, whereas diversity signified cultural learning (Crivelli and Fridlund 2018). To the contrary, diversity may equally arise from phylogenesis (Darwin’s *adaptive radiation*) and commonalities from cultural learning (*convergent cultural evolution*). Buss (2014) questioned using universality among humans and presence among nonhuman primates, as criteria for determining the “basicness” of emotions, when (1) “jealousy” was not on any basic emotion list and (2) traits that were unquestionably phylogenetic often span very few species (e.g., ultrasonic echolocation, documented only among microchiropteran bats).

Contemporary Research Agenda

The most important advance in psychology's study of facial behavior may lie in the sophistication of its inquiry. Questions loaded with presuppositions (Does this society "recognize" the "basic emotions" from these posed faces?) are being replaced with more neutral questions, such as (1) What facial behavior occurs? (2) In what context does it occur? (3) How does that behavior influence an observer? (4) What about the observer and context leads him or her to react in that way? Of course, faces of emitters and observers quickly form a reciprocal interaction loop.

Childhood development. What facial behavior is seen in early development? One researcher made diaries and video records of her daughter's facial behavior over 8 weeks and found notable departures from basic emotion theory's predictions. For example, similar stimuli frequently elicited wholly different facial behaviors, and "distress-pain" faces occurred during bathing with no obvious distress (the body of research supporting this conclusion is summarized by Camras et al.; in Fernández-Dols and Russell 2017).

Studies of infants concluded that even neonates respond to facial behavior, and habituation studies showed that infants can even discriminate among different facial configurations. Still, two more specific issues remain unresolved. The first concerns whether neonates can imitate facial behavior, and one question hinges on whether certain neonatal facial behaviors that were considered frank imitation instead signify mere arousal produced by the model's behavior (see Meltzoff et al. 2017; and Oostenbroke et al. 2016, for opposing views). The second issue concerns when children learn to apply their culture's emotion concepts to faces. It appears that young children begin by making valence-based (good vs. bad) attributions and use more differentiated emotion labels increasingly over the preteen years (Widen, in Fernández-Dols and Russell 2017).

The bivalent way that young children react to facial behavior is readily seen in infant social referencing, in which infants as early as

6 months who confront conflict or ambiguity (e.g., in traversing a visual cliff) use the facial behavior of a caretaker to guide how they respond. Caretaker smiles are cues to engage or proceed, while frowns promote disengagement or retreat (Feinman 1992). Maturation brings sharper discernment of others' facial behavior. Joint attention, or following another's gaze, may predict where the emitter goes or what he or she talks about next. Others' facial actions may suggest people's intentions, dispositions, or what they will say when asked, "How are you feeling?"

Signaling. Ethologists long stressed the signaling role of behavior in animal communication. Might our facial behaviors have evolved as *signals*, rather than having "devolved" (degenerated) to mere residues of once functional acts as Darwin proposed? That was the conclusion from early twentieth-century avian observations by Heinroth and Huxley, who suggested that behaviors used as signals evolved to be more conspicuous by prior selection for their predictive value. These *displays* tended to be ones that preceded overt acts (e.g., baring teeth before biting) and foreshadowed the acts themselves. Teeth baring, through natural selection, would become more dramatized and conspicuous and increasingly independent of its origins in biting. Such *intention movements* (Heinroth) were thus said to become displays by *ritualization* and *emancipation* (Huxley). An analogous process – *conventionalization* – results from cultural rather than natural selection (Smith 1977).

These ritualized actions are potentially beneficial for both emitter and observer: conspicuous tooth baring alerts an interloper that I may pounce and bite, so that the interloper flees and neither of us draws blood. Krebs and Dawkins (1984) characterized the coevolution of displays and vigilance as a signaling ecology which, like many social strategies, is probabilistic; it will be leveraged by deceivers who may force the evolution of more "honest" (i.e., predictive) displays, but the signaling ecology nonetheless carries overall reproductive benefits.

Might human facial behavior be conceived similarly? Noting that ethology had jettisoned the earlier view that animal signals were

stereotyped and “released” and now considered them contextual and strategic, Fridlund (1994) suggested that human facial displays might work identically. He proposed the *Behavioral Ecology View* of facial behaviors, reconceiving them as “social tools” which serve as cues of contingent action in social negotiation. This view suggested a functionalist, externalist approach to research in which constructs like “emotion” were unnecessary detours.

The approach has seen wide application. One contemporary effort is in artificial intelligence (AI), where the task is to understand everyday interactive facial behavior and then simulate it using embodied computerized agents. Although most software efforts have been benchmarked on “recognition” of iconic “expressions of emotion,” doubts about the usefulness of this approach have arisen, and AI alternatives based on the functionalist behavioral ecology view have been proposed (Crivelli and Fridlund 2018).

Miming and deception. Like stage actors, people in everyday impression management adjust their facial behavior with their social role transitions, e.g., from partner to parent to employee. As Goffman (1959) noted, it is often difficult to separate non-acting from this “miming” or frank pretense. Indeed, the facial muscles are sometimes termed the *mimetic* muscles.

One unexpected instance of miming may be “showing empathy.” Bavelas et al. (1986) analyzed dyadic conversations and found that listeners produced facial movements like those of speakers, not by reproducing the speakers’ sentiments but to convey understanding of those sentiments; thus, empathic facial behavior needs not be “feeling as you do” but “showing you how you feel.”

It’s a thin line between pretending and deceiving, and detecting deception via the face has been a consistent theme in facial behavior research. Despite several claims, research has failed to substantiate any reliable facial signs of deception or inauthenticity (Vrij et al. 2011).

Signs. Much of our facial behavior (1) aids in regulating respiration, lacrimation, olfaction, vision and light adaptation, food ingestion or

expulsion, and speech articulation; (2) is recruited in protective reflexes like coughing, sneezing, blinking, and nose wrinkling; and (3) is involved in homeostatic adjustments like yawning, burping, and vomiting. Some so-called “expressive” facial behavior may simply be “given off” in the process (e.g., widening the eyes takes in more light, and flaring the nostrils takes in more scent; Lee and Anderson, in Fernández-Dols and Russell 2017; Susskind et al. 2008). In this way, research is returning us to Darwin’s non-communicative view of facial behavior.

Appraisals. Some theories posit that facial behavior results from information processing beyond mere registration of the situation. Several *appraisal theories* assume the basic emotion theory’s “emotion program” but contend it is triggered by prior appraisal. Other such theories treat “emotion” as a folk concept rather than a scientific one, and for these theories, an “emotion episode” results from a series of appraisals of one’s situation which leads to reactions that include facial behavior. Such constituent appraisals may be (1) bottom-up (stimulus-driven) or top-down (based on preconceptions from one’s interaction history), and (2) fast and automatic or slow and integrated with other cognition.

Appraisals, these theories hold, are made along dimensions such as novelty, valence, goal relevance, goal congruence, certainty, coping potential, and agency. Each appraisal dimension has separate and independent effects on facial behavior: novelty results in eye widening, positive valence in smiling, and so on. The large number of possible appraisal patterns implies commensurately numerous patterns of facial behavior, from which observers may make inferences about the emitter (Scherer et al., in Fernández-Dols and Russell 2017).

Conclusion

Scientific work on human facial behavior has advanced by the slow, painful abrogation of long-standing presuppositions, both explicit and implicit. This research has brought home the fact

that approaches to facial behavior based on received wisdom, assumed subpersonal events, posed faces, and categorical emotions will be insufficient to understand how that behavior arises and functions in social interaction and how to simulate it in our future android interactants. These questions and others dovetail with new interdisciplinary efforts that combine psychologists with specialists in fields that include anthropology, biology, biomedical engineering, communications, computer science, the history of science, and the neurosciences. The result is the emergence of fundamentally different conceptions about human facial behavior and the ways to study it.

Facial Resemblance and Kinship Detection by Strangers

Nadja Richter
Institute of Child Development, University of Minnesota, Minneapolis, MN, USA

Synonyms

[Phenotypic similarity](#); [Physical self-similarity](#); [Visual similarity](#)

Definitions

Facial resemblance

- Amount of physical similarity between individuals' facial features.

Kinship detection

- Assessment of the degree of relatedness or genetic similarity among individuals.

Introduction

Human sociality is characterized by cooperation within large social groups. These groups often contain a large fraction of people not personally known to a given individual. It has been proposed that, in the absence of any knowledge about a prospective social partner, the detection of morphological similarity potentially underlies social assortment among strangers. The objective of the following is to provide a brief overview on recent findings on the role of facial resemblance in guiding human social preferences.

Humans Prefer Similar Others

Humans have evolved to form and live within large and complex social systems. They are exceptional in the extent to which they engage in cooperative exchange, even with strangers. This human-specific feature has been viewed as a challenge for evolutionary explanations of cooperative behavior – that it must be established through benefiting both the individual and the inclusive fitness of the cooperator, e.g., by cooperating with an individual's offspring. In order to maintain complex societies, cooperative actions and prosociality need to be directed toward likely cooperators, i.e., individuals that will likely reciprocate the behavior toward a common, group-benefiting goal. Cooperative actions need to be directed away from likely defectors, i.e., individuals who benefit from altruistic acts without reciprocating. Defining oneself not only as an individual but also as a member of a cooperative group seems a key feature of human psychology. However, in order to maintain cooperation and prosocial behavior, the individual needs to be able to recognize likely cooperative interaction partners.

During human evolution, social networks increased to a size where individuals were more likely to encounter unfamiliar than familiar others. Faced with large numbers of strangers, which cues guide individuals to select and deselect others and to focus discriminatory attention on certain others? One such cue that can influence social assortment is the perceived level of similarity. It has been argued that choosing to cooperate with more similar strangers maximized the chance of successful cooperative interactions as because similar individuals were more likely to share relevant behavioral tendencies (McElreath et al. 2003).

In various experimental settings, it was shown that adults trust and prefer others more that resemble themselves with regard to facial similarity, a tendency that has been interpreted as a consequence of an adapted kinship detection mechanism (DeBruine 2002; Bressan and Kramer 2015). These findings suggest that the detection of morphological similarities potentially underlies social assortment among strangers.

Perception and Use of Facial Similarity in Others

The closer related two persons are, the more genes they share, and the more similar they will look. Because craniofacial morphology is highly heritable (Djordjevic et al. 2016), genetic similarity between individuals tends to be expressed as phenotypic similarity. From early in life, humans are able to categorize their conspecifics by facial resemblance (especially those of the same sex, age, or ethnicity) and to discriminate among kinship relationships via facial phenotype. Thus, facial morphology appears to be a prominent cue for ascribing familiarity and relatedness among individuals, and facial resemblance is most likely the most commonly used physical cue of kinship (DeBruine et al. 2007).

Various experimental studies have shown that adults can detect kinship among strangers from facial portraits. For example, in simple matching tasks, participants are able to correctly associate siblings with one another (Maloney and Dal Martello 2006). Likewise in third-party judgments of pictured stranger faces, humans can reliably assess the relatedness of close (i.e., parent/child) and distant kin (i.e., grandparents/grandchildren, aunt/uncle and nephew, as well as cousins) (Alvergne et al. 2010; Kaminski et al. 2009).

A few experiments have further directly studied the effects of facial self-resemblance on social behavior in adults and demonstrated that people have more positive evaluations of faces that subtly resemble themselves and familiar others. Usually set up within economic game contexts, the participants were provided with pictures of their ostensible partners while unaware that these pictures had been manipulated to look like themselves. Typically, in such experimental manipulations, image transformation software had been used. Using the tool of “morphing,” these programs allow for digitally altering portrait pictures. Specifically, by blending in the facial features (shape, color, and texture information) of two or more facial pictures, a novel composite face is created that resembles its input faces to a certain degree. To ensure that participants are unaware of that manipulation, the morphed faces usually consist

of 40% or less of their own face, a threshold at which subjects generally do not detect their own facial features in the composite morph. Such subtle cues of experimentally manipulated self-resemblance increase perceived trustworthiness in strangers (DeBruine 2002; Verosky and Todorov 2013) and decrease perceived attractiveness of opposite-sex stranger faces (DeBruine et al. 2007). It was also shown that people are more likely to vote for unknown political candidates whose faces have been manipulated to subtly resemble their own faces (Bailenson et al. 2009). Further, the presence of slightly self-similar faces in a group of strangers promotes cooperation for the public good in an experimental setting where participants can choose how much to invest (Krupp et al. 2008). Interestingly, humans are sensitive to negative relatedness cues as well. Krupp et al. (2012) have shown that faces that deviate from the average in a direction opposite to one's own face are judged less attractive and less trustworthy.

However, all these works exclusively used adult participants to explore effects of facial resemblance. In order to argue for this preference to be an evolutionary adapted behavior, one needs a better understanding of its ontogenetic emergence and functional mechanism. Face processing matures fully during early childhood and children constantly interact with unknown others, so it is likely that already at a young age, they sensitive to morphological self-similarity in unfamiliar peers.

A study by Kaminski et al. (2013) investigated a slightly different skill in 5- to 11-year-old children, namely, their ability to detect mother-offspring resemblance in faces of unknown others. Their findings show that by the age of 9, but not younger, children could efficiently match a newborn's face with that of his/her birth mother. Thus, the ability to discriminate kinship in unknown others via perceptually salient facial features does not fully develop until middle school age.

Yet surprisingly, preschoolers at the age of 5 years already use facial self-resemblance when they make social judgments about unknown others (Richter et al. 2016). In the absence of any additional knowledge about prospective peers, children preferred those who look subtly like themselves over complete strangers. However, the correspondence

between detection of self-similarity and social preferences is not perfect – the 5-year-olds in that study reliably detected resemblance to their own face, but they did not always use this information in their social preferences (Richter et al. 2016). It thus remains an interesting challenge for future studies to further investigate the specific cognitive mechanisms underlying the effects of facial self-resemblance preferences.

Summary

Various studies have shown that morphological similarities trigger social preferences. Even slight facial self-resemblance, a subtle cue of kinship, is a salient cue that promotes prosociality and trust toward unknown others. As has been shown recently, such responsiveness to self-similarity seems to be present already early in life. For example, preschoolers at the age of 5 years use facial resemblance when making social judgments about unknown others. Thus, the tendency to select social partners based on facial similarity begins well before adulthood, and facial similarity is a strong guide to social assortment, especially when any other useful information about the potential interaction partner is missing.

Facial Width to Height Ratio and Dominance

Barnaby J. W. Dixon

Queensland, Brisbane, QLD, Australia

Synonyms

Aggressiveness; FWHR; Prestige; Social status

Definition

The facial width-to-hip ratio (FWHR) is an anthropometric measure of facial shape. It is calculated by taking the distance from one zygion to the other and dividing it by facial height. Dominance refers to an individual's position within a social hierarchy, while dominant behavior describes a number of traits including, but not restricted to, inflexibility, drive for achievement or power, and controlling the behavior of others.

Introduction

Natural selection has shaped the evolution of human visual systems to be highly attuned to extracting socially relevant information, such as age, ethnicity, gender, and emotions from the face (Little et al. 2011). While interpreting facial expressions and displays of emotion are of critical importance during human interpersonal interactions, static facial cues also provide meaningful information relating to sexual maturity and a healthy endocrine system that influence interpersonal interactions (Little et al. 2011). Sexual selection may also have shaped the evolution of face perceptions to extract relevant information from same-sex rivals or in the opposite sex for mate selection purposes. This chapter briefly summarizes some recent research detailing the role of craniofacial morphology in determining dominance and intra-sexual competition.

Sexual Dimorphism in Craniofacial Shape and FHWR

Men and women differ in a number of craniofacial and cutaneous facial characteristics, owing largely to the effects of sex hormones during development (Dixon et al. 2016). Male typical facial shape, or facial masculinity, includes a larger brow ridge, thicker jawline, narrower eyes, and a more robust midface than is typical in women (Whitehouse et al. 2015). Facial masculinity may develop due to organizational effects of androgens during fetal development that are most likely

activated during pubertal androgenic surges (Whitehouse et al. 2015).

One component of facial masculinity is the facial width-to-height ratio (FHWR), which is calculated by taking the distance from one zygion to the other and dividing it by facial height (Geniole et al. 2015). Interestingly, FWHR in adulthood is not associated with fetal androgens (Whitehouse et al. 2015), variation in androgens during adolescence (Hodges-Simeon et al. 2016), or current levels of testosterone in adulthood (Whitehouse et al. 2015; Bird et al. 2016). Analyses of 4,740 female and 6,133 male FWHRs revealed that the FWHR is sexually dimorphic, being larger in men than women, although the size of this effect was small ($d = 0.11$; Geniole et al. 2015). However, recent meta-analyses suggest no sex differences in FWHR (Kramer 2016). The following sections will review the role of male FWHR in communicating attractiveness to opposite sex and formidability to members of the same sex in order to place its importance in the context of human evolution via sexual selection.

Sexual Selection and FWHR as an Intra-sexual Cue of Dominance

Sexual selection is a form of natural selection that occurs when individuals are in competition for mates (Kokko et al. 2006). One of the consequences of sexual selection is the evolution of sexually dimorphic morphological features that function in mate attraction or mate competition (Kokko et al. 2006). Sexually selected traits can be ornamental, serving to attract members of the opposite sex via intersexual selection, or be badges of status or weaponry employed during same-sex or intra-sexual displays of dominance and aggressiveness (Dixon et al. 2005).

Men's FWHRs may be marginally larger, on average, than women's (Geniole et al. 2016; but see Kramer 2016), and larger FWHRs are judged as more masculine than smaller FWHRs in male but not female faces (Geniole et al. 2015). Interestingly, while some studies have reported that male FWHRs are positively associated with reproductive success, men's FWHR is negatively

associated with women's judgments of male facial attractiveness (Geniole et al. 2015), suggesting that female choice may not have shaped the evolution of men's FWHRs.

Sexual dimorphism in body size is often attributed to effects of sexual selection via intra-sexual competition among anthropoid primates (Dixon et al. 2005). Facial and bodily attributes may provide information relating to body size and function in concert during behavioral displays. FWHR in both women and men is indeed positively associated with BMI (Geniole et al. 2015), suggesting a role of FWHR in intra-sexual displays of dominance and in direct agonistic contests. Ratings of dominance and threat are positively associated with male and female FWHR (Geniole et al. 2015) and are likely independent of beardedness (Geniole and McCormick 2015), which is a strong determinant of perceived male dominance and aggressiveness (Dixon and Vasey 2012). It is important to note that the positive associations between male FWHR and ratings of masculinity, dominance, and aggressiveness are stronger when derived from natural faces than when using composites, avatars, and other artificially generated faces that manipulated FWHR (Geniole et al. 2015). Nonetheless, threat and dominance were still positively influenced by FWHR in studies using artificially manipulated stimuli (Geniole et al. 2015).

Evidence from Behavioral Studies that FWHR Is an Intra-sexual Cue of Dominance

If FWHR is of importance to understanding intra-sexual competition, then it should be a predictor of outcomes in dominance-related and agonistic interactions between men. There is some evidence that men with more robust midfaces have greater muscularity (Holzleitner and Perrett 2016) and FWHR is positively associated with BMI (Geniole et al. 2015). In studies of mixed martial arts fights, larger FWHRs were positively associated with fighting performance (Geniole et al. 2015; Haselhuhn et al. 2015). Similarly, in professional ice hockey, more aggressive males who spent longer in the penalty box following foul plays had larger

FWHRs (Geniole et al. 2015; Haselhuhn et al. 2015). Finally, in a study spanning 32 nations competing in the 2010 soccer world cup, aggressiveness was positively associated with FWHR in midfield and forward players (Geniole et al. 2015). Although some studies have not replicated the association between male aggressiveness and FWHR, meta-analyses have found that when taking the literature as a whole, men with larger FWHRs are more aggressive in sporting contests (Geniole et al. 2015; Haselhuhn et al. 2015).

In addition to aggressiveness in sporting contests, men with larger FWHRs behave in more socially dominant ways in business negotiations (Geniole et al. 2015). For example, a CEO's ability to achieve returns on assets, a seller's ability to achieve high sales prices, and an individual's ability to negotiate a salary bonus were all more likely to be higher among men with larger FWRs (Geniole et al. 2015). Men with larger FWHRs are also significantly more selfish and pejorative than men with smaller FWHRs (Geniole et al. 2015). These findings, coupled with evidence that men with larger FWHRs also have higher self-ratings of social dominance and are judged as looking for socially dominant by naïve raters than men with smaller FWHRs, suggest this metric of facial shape to be associated with dimensions of social dominance and threat (Geniole et al. 2015; Haselhuhn et al. 2015).

Conclusion

One criticism of using ratios in studies linking morphology to biological, behavioral, and social outcomes is that these measures are derived from complex multivariate phenotypes. For example, while a large literature has focused on how the waist-to-hip ratio (WHR) determines bodily attractiveness, multivariate analyses have shown that effects of WHR are likely due to selection acting on multiple components of shape rather than a discrete ratio (Brooks et al. 2015). Associations between FWHR and dominance may occur as a consequence of trait interactions, as it reflects a discrete measure that forms part of a multivariate measure of facial masculinity. However, there is

some evidence that male FWHR is a stronger predictor of dominance than a measure of facial masculinity (Lefevre et al. 2014; but see Dixon et al. 2016 for mixed results). Further studies placing the FWHR within a multivariate context would be valuable. Finally, it remains to be determined whether any of the findings relating FWHR to male dominance and formidability extend to small-scale societies wherein behavior manifests in ecological settings that are closer to those of human ancestry than modern multilevel and often industrialized cultures. For the present, the FWHR appears to be larger in men who are more behaviorally dominant and are judged as looking more dominant, but not more physically attractive, suggesting a role of intra-sexual selection shaping masculine facial robustness.

Factors Associated with Suicide

Brian M. Bird
Department of Psychology, Simon Fraser
University, Burnaby, BC, Canada

Synonyms

Gestures of despair; Self-destruction; Self-sacrifice

Definition

The act of taking one's life.

Introduction

On the surface, suicide seems to pose a problem for the idea that humans seek to maximize their own fitness (i.e., pass on their own genes). In fact, it could be argued that suicide serves the exact opposite purpose—to maximally reduce fitness by completely eliminating any future chance of passing on one's genes directly. However, an evolutionary perspective on suicide might suggest otherwise. The elimination of one's life does not necessarily preclude the propagation of one's genes, as individuals with shared genes may be able to still successfully reproduce. Therefore, there may be an important trade-off between the reproductive costs and benefits that accompany a suicidal act.

Humans evolved in largely social contexts that required a high degree of cooperation. In such environments, there would be certain behavioral alternatives that could change the cost-benefit ratio of actions to favor those most beneficial for a group, rather than for a single individual. An inclusive fitness perspective on suicide incorporates this idea by identifying factors that go beyond self-survival and instead emphasizes the idea that suicide may actually help genetic transmission if it can increase the likelihood that other individuals with shared genetic makeup can pass on their genes. More specifically, this phenomenon can be explained by kin selection—the idea that fitness loss by an individual may be valuable if it is followed by a compensatory increase in fitness for close relatives. Some of the most common factors associated with understanding suicide from this, and other evolutionary views, are outlined below.

Reduced Ability to Contribute to One's Fitness, and Perceived Burdensomeness to Kin

In a series of seminal literature pieces spearheaded by Dr. Denys deCatanaro (e.g., deCatanaro 1986, 1995), it was argued that suicide is most

probable for individuals that have a significantly reduced ability to contribute to their own fitness. In this case, the reduced ability for fitness contribution is thought to relate to many factors, including current poor health or expectations of future poor health (e.g., older individuals), low prospects for reproduction with opposite sex partners (e.g., individuals who are single, widowed, divorced, low in mate value, or reporting low romantic relationship satisfaction), and, perhaps most notably, perceived burdensomeness to kin. Indeed, results of empirical studies show support for the idea that suicidal ideation—thought of as a proxy for suicidal behavior, given that suicide is often preceded by ideation—is, for example, positively correlated with perceived burdensomeness, and negatively correlated with recent or lifetime heterosexual sex, success and stability in heterosexual relations, and number of children. deCatanaro's research also demonstrates that concerns about health burdens receive increased importance in older individuals, and that this perceived burden is also associated with suicidal ideation. Many other empirical investigations, including clinical studies and direct tests of this model, have also provided support for deCatanaro's idea by showing that perceived burdensomeness is a stronger predictor of suicide than emotional pain (e.g., van Order et al. 2006).

Parent-Offspring Conflict

Suicidal behavior, at least among adolescents, has been proposed to act as a negotiating tactic to promote greater parental investment to particular offspring. In this case, the goal of the behavior is not death, but rather the signal of "need" to parental figures. Although this explanatory factor has received less attention than the inclusive fitness model, there is some evidence to support it. Andrews and colleagues (2006) tested this idea using a sample of over 1600 adolescents. Findings revealed that adolescent dissatisfaction with the mother predicted suicide attempts 1–2 years later. However, there was also evidence that middle-born adolescents made fewer attempts than offspring in different birth orders, yet those attempts made by the middle-born offspring were more severe than the other siblings. This finding was interpreted as

potentially supporting other research showing that middle-born children are in a disfavored position (e.g., mother feels least close to them, child feels least close to mother, less quality parental time spent with the middle child), therefore requiring the middle-born child to take more severe risks. The more severe attempts (yet seemingly paradoxical lower number of attempts) by these middle-born offspring might suggest that the value of increased parental investment is weighed carefully against the risks of death. Thus, suicidal ideation may be a tactic to assess parental sensitivity to risk, the feedback from which can then be used to determine the relative cost in the risk of dying, and finally to create a plan where “the risk matches the threshold needed to compel parental capitulation” (Andrews 2006, p. 206).

Suicide as a By-Product of Bargaining

Suicidal gestures (e.g., self-harm, attempts not ending in death) may also be used as a cry for help in situations requiring the attention of other members of a social group. At first glance, a suicidal gesture seems unnecessary, as there are less costly ways to signal need to another individual (e.g., verbal expressions, acts of crying). However, if relations between social partners are not strong, the less costly methods may be insufficient to garner attention and may therefore require more drastic actions to convince seemingly distant social partners that the need is in fact genuine (Hagen et al. 2008). By the suicidal individual making their requirements explicitly known, others may recognize these unmet needs and be put in a position where they are forced to act. While the need to act might be unnecessary in some cases in the modern environment, the environment in which our species evolved would have involved tightly knit social groups, with largely family-based organizations. Thus, *not* acting on such behavior would have likely had greater consequences.

It is important to note that the suicidal gesture in this case can impose costs on the receivers (i.e., social partners) in the sense that the receivers may rely on the contribution and productivity of the individual to the group as a whole. Therefore, the

motivation to help an individual in need (i.e., the one making suicidal gestures) may be to strengthen the productivity of the group as a whole, which may include helping and attending to the needs of the suicidal individual. These types of personal interactions are often thought to be bargaining strategies in that suicidal gestures threaten the benefits to other members (especially in the case where the suicidal individual has a monopoly on benefits provided to the group), therefore compelling members of the group to negotiate with the individual; the ultimate goal, here, is to have a mutually beneficial arrangement (i.e., the bargaining model). That is, suicidal gestures function to give the suicidal individual help and support from members of the social group, while the social group receives the benefit and cooperation from someone who is no longer incapacitated by despair. In short, individuals may make suicidal gestures when they suffer higher costs that can be relieved by others in the group; with the threat of social losses, the benefits for members of the social group to help the suffering individual may outweigh the costs of not helping them.

So how does bargaining with suicidal gestures serve as a factor related to actual suicide? Evidence indicates that suicidal gestures significantly predict actual suicide attempts and completed suicide later on (e.g., Prinstein et al. 2008; for additional evidence, see a brief review by Syme et al. 2015). Therefore, it is possible that acts of suicide completion are simply an accidental byproduct of dangerous forms of self-harm, and especially following repeated acts of self-harm (e.g., Zahl and Hawton 2004). In contrast to models subscribing to inclusive fitness, this model suggests that completed suicide is simply an accidental by-product of suicidal bargaining gestures, rather than an act resulting in death whereby fitness benefits are promoted through surviving kin.

Comparing Theories of Factors Leading to Suicide

Some recent research has explicitly tested the inclusive fitness and bargaining models against

one another to help understand what evolutionary factors might be most associated with suicide. Using data collected from 53 cultures, Syme and colleagues (2015) undertook an impressive analysis of nearly 475 accounts of suicide from ethnographic material spanning multiple centuries. Results from this work revealed some evidence for the inclusive fitness model in finding that after controlling for the lethality of a suicide attempt, 13.9 % of records fit this explanation. Furthermore, 30.2 % of the cultures showed evidence that at least some of the victims were perceived to be a burden on others. Perhaps more convincingly, however, was evidence for the bargaining model, in which 80.6 % of records showed at least one variable that included evidence from this model.

Suicide Terrorism

Liddle and colleagues (2011) have provided an evolutionary framework for a specific form of suicide called suicide terrorism. In the same way that suicide may be a way of helping genetically related kin, suicide terrorism may simply be the malfunction of a mechanism that was designed to help kin, and instead is used as a means to help one's genetically unrelated group (e.g., religious group, although this is nonetheless a close group—sometimes considered “fictive kin”). As with other forms of suicide, for such a behavior to be advantageous in some way, the benefits to “kin” (i.e., group members) must outweigh the costs. Liddle and colleagues suggest that religious beliefs may play a partial role in facilitating these acts, because without the belief that life continues after death, the costs of such an act (e.g., death) may outweigh the benefits. In this and other ways, religious beliefs may be a factor associated with acts of suicide terrorism. However, it should be noted that religious belief on its own is not inherently related to suicide terrorism, but rather, it may be a catalyst to such an act in some cases.

Conclusion

A number of evolutionary models have been proposed to explain factors associated with suicide—a

seemingly paradoxical act for a species where individuals seek to maximize their fitness. It is possible that suicidal behavior may not have been entirely maladaptive in the ancestral past, given that individuals with shared genetic makeup could still pass on their genes via genetically related kin. Further, suicidal gestures may have been useful as a bargaining tool for increasing parental investment, or increasing attention from social partners, but may have sometimes resulted in death as a by-product of such behavior. Despite some compelling findings over the past few decades for each of these models, future research will be needed to shed further light on the theorized factors associated with suicide, as well as other potential interactions between specific factors identified by such theories (e.g., interactions between perceived burdensomeness and reproductive potential; for recent evidence, see Brown et al. 2009) and how other specific forms of suicide (e.g., suicide terrorism) are related to evolved mechanisms, or the malfunctioning of such mechanisms.

Definitions

Bullying includes behaviors influenced by various internal and external factors to intentionally harm

weaker individuals and adaptively obtain resources (Volk et al. 2014).

Introduction: Bullying and Ecological Systems

Bullying is a behavior that can be adaptive under various ecological systems. Under these conditions, bullying may be used to obtain material, social, and reproductive resources (Volk et al. 2014). In the microsystem, or most proximal factors, an individual's characteristics and direct relations with parents and peers can influence bullying (Bronfenbrenner 1979). Beyond the microsystem, factors in the mesosystem or interactions between social relationships can affect competitive climates that facilitate bullying. Such climates can be embedded into the exosystem, or system of more distal community environments, and the macrosystem, which includes cultural norms. Finally, major life events in the widest chronosystem may influence bullying.

Age

At the innermost microsystem, the sociodemographic characteristics of an individual may influence bullying. During childhood, direct physical and verbal bullying behaviors are most common (Volk et al. 2016). As individuals transition into adolescence, there is increasing social and sexual competition that coincides with the start of puberty and high school. Consequently, the benefits of establishing dominance through maximizing victim harm may increase the prevalence of bullying, with approximately 30–40% of adolescents involved (Volk et al. 2016). Moreover, cognitive advancements with age allows for an increase in strategic, complex covert bullying, such as social exclusion or gossiping, that minimize perpetrator identification and victim retaliation (Volk et al. 2016). The strategic use of various forms of bullying is also evident in sex differences.

Sex

Sex is another important individual characteristic in the microsystem that reflects the differential

selection pressures consistent with the sexual selection and parental investment theories (Trivers 1972). In particular, males often bully out-group members to strengthen in-group cohesiveness (Volk et al. 2014, 2016). A solid in-group allows males to engage in riskier, direct physical and verbal behaviors. Demonstrating such strength can deter out-group members from challenging the male alliance (Volk et al. 2014, 2016). Also, the tough status may signal the ability to protect prospective opposite-sex mates and offspring. Thus, direct forms of bullying may provide adolescent and adult males with important social and reproductive goals. Contrarily, given that females may encounter reproductively costly risks when using direct bullying, they may prefer indirect behaviors as a means to strategically enhance their own status while targeting a rival female's promiscuity (Volk et al. 2016). Through indirect behaviors, females can create exclusive popular in-groups comprising of high status males, from which they can pick the best suitor (Volk et al. 2016). Males and females with certain personality traits may also strategically use bullying.

Personality

Personality is a third important intrinsic factor in the microsystem and is associated with genetic predispositions that may facilitate bullying (Book et al. 2012). Individuals with particular traits may find bullying is more adaptive and use it more frequently. For instance, studies on temperament found children higher in callousness and lower in empathy were more likely to bully than children lower and higher in these two traits, respectively (Book et al. 2012). Likewise, studies on the Big Five personality found children less agreeable, more emotional, and less conscientious also bullied more. Recently, studies used the HEXACO personality model to investigate adolescent bullying and found those lower in Honesty-Humility, which encompasses strategic exploitation of others, had higher perpetration of global (e.g., Book et al. 2012) and verbal, social, and racial forms of bullying (Farrell et al. 2014).

Individuals who have a predisposition to selectively exploit may be more likely to use bullying, a behavior characterized by adaptively harming others. Beyond an individual's sociodemographic and personality characteristics, external social relationships in the micro- and mesosystems can also influence bullying.

Parenting

Children often form their first social relationship with parents, and therefore, parents can set the basis for acceptable behaviors in future relationships. Thus, parenting can be a direct relationship influencing children in the microsystem, but also interact with wider relationships including peers, teachers, and schools to comprise a factor in the mesosystem. Authoritarian parenting styles characterized by low warmth and responsiveness often predict child aggressive behaviors including bullying (e.g., Baldry and Farrington 2000). Such parenting styles may directly model aggressive behaviors, but also indirectly model a lack of concern for others, which can facilitate behaviors that inflict harm on victims without remorse (Volk et al. 2016). Directly and indirectly facilitating bullying via parenting behaviors is consistent with the evolutionary notion that parents demonstrate behaviors that can lead to resource acquisition for survival. This acquisition serves to directly benefit children, but also indirectly benefit parents through offspring survival and securing genetic proliferation (Trivers 1972). Thus, children and adolescents may adaptively use bullying behaviors with peers during times of heightened competition for resources.

Peers

As children age, peers play a primary role in socialization within the microsystem, while parents begin to play a secondary role. Similar to parenting, peers can be a direct influence in the microsystem, but interact with parents, teachers, and schools to influence within the mesosystem. The start of high school is a heightened time of

competition for limited dominant roles in a newly forming peer network (Volk et al. 2016). Peer group dynamics beyond a single bully and victim can influence bullying. For instance, when popular adolescents used bullying to achieve status, peers viewed bullying as a productive strategy to obtain a desired goal (Dijkstra et al. 2008). Consequently, individuals in the peer network may then encourage the use of similar bullying behaviors as a method to obtain valued goals. This may be one reason why the wider peer network often view bullying as a negative behavior, but still play direct roles as bullies or indirect roles as assistants, bystanders, and reinforcers. Moreover, the moderating role of popularity may explain why on average adolescents who use aggressive behaviors are rejected, but when the same behaviors are used strategically by popular adolescents are associated with high social status (Dijkstra et al. 2008). Thus, status goals can be achieved through bullying behaviors, but in combination with peer-valued characteristics. Bullying in the absence of these valued characteristics may result in peer rejection. In sum, it appears that a few, key popular individuals can set bullying norms within a peer group (Dijkstra et al. 2008). However, these peer norms may be only one important factor embedded in the broader school climate.

School

The school is a wider factor in the mesosystem that incorporates interactions between the individual and their immediate relationships within the microsystem, including peers. Since adolescents spend the majority of their time in school with peers, several aspects of the school atmosphere may facilitate bullying. For instance, teacher anti-bullying attitudes may influence classroom bullying (Volk et al. 2016). Teachers who are perceived as effective at decreasing bullying by their students had classes with lower peer-reported bullying (Volk et al. 2016). Accordingly, teachers can model antibullying attitudes and behaviors, which can enhance prosocial behavior and also decrease bullying. Teacher and student attitudes can also

affect wider climates of school competition, which can influence bullying.

In a highly competitive school environment, bullying can be used to establish social and/or tangible resources (Volk et al. 2016). Schools with a highly competitive atmosphere may facilitate dominance hierarchies based on social status through popularity or academic status through grades or scholarships (Volk et al. 2014). These hierarchies may encourage students to assess their social and/or academic abilities relative to one another (Volk et al. 2014, 2016). Adolescents with higher abilities may then adaptively exploit this evaluation by bullying individuals with lower abilities to maintain higher rank. In fact, classes with a few, key popular adolescent bullies often had higher levels of classroom bullying, with poorer quality of peer relationships (Dijkstra et al. 2008). Bullying to compete for limited school resources mimics the advantages of bullying for survival evident in competitive historic hunter-gather societies with scarce food resources (Volk et al. 2014). Although to a lesser degree, bullying in competitive schools reflects the evolutionary advantages of bullying for limited resources. Competition can also extend to the distal exo- and macrosystems, which can directly and indirectly influence bullying.

Community

Similar to a school, including relationships from the microsystem, the community is an even wider ecological factor that incorporates the previous micro- and mesosystems. The community can be considered a part of the exosystem since an individual plays an active role but does not directly influence it. Additionally, the community can be considered a part of the macrosystem since it encompasses broader cultural norms (Hong and Espelage 2012). In particular, community inequality may influence bullying at both the exo- and macrosystems.

Several studies on income inequality found higher inequality within a community and/or school was associated with higher levels bullying (Elgar et al. 2013). The actual degree of inequality

reflects the exosystem, while the underlying power imbalances and competitive cultural norms reflect the macrosystem. Consequently, at both systems, bullying may be influenced by the prospective financial and material gains in communities with high inequality. This is again similar to the adaptive, survival-based benefits of bullying in historic societies with scarce resources (Volk et al. 2014, 2016). Moreover, researchers suggest that some cultures and political regions that promote competition and oppression of particular ethnicities, disabilities, sexual orientations, genders, and socioeconomic backgrounds may have higher bullying perpetration, since it is a culturally accepted method to reinforce hierarchies (Hong and Espelage 2012). Thus, bullies may learn to exploit their ethnic, cultural, or economic advantage from their parents at home, and peers and adults at school, who may also share and use these advantages. On the contrary, individuals may have little to gain from bullying in communities where residents have relatively equal access to resources. Instead, bullies in these equal communities may experience greater costs, including disapproval or punishments from community members. Taken together, distal community factors are interconnected with proximal factors that can influence bullying at both an economic and cultural level.

Life Changes

At the broadest level, the chronosystem includes major life changes (Bronfenbrenner 1979; Hong and Espelage 2012). These changes can be normative, such as starting high school, and also nonnormative, such as a family death (Bronfenbrenner 1979). The chronosystem also incorporates previous ecological systems. At the narrowest level, this system accounts for an individual's age and cohort effects with respect to event timing. The changes can also occur within relationships from the microsystem (e.g., changes in family) or at the macrosystem (e.g., changes in political structure; Bronfenbrenner 1979). For example, evidence suggests that major family restructuring such as parental divorce has been linked to lower self-regulation (i.e., personality

changes) and higher aggression in children (Hong and Espelage 2012). These changes may signal to children instability, and consequently more prospective gains of bullying. Thus, major changes in life events may influence bullying directly but also indirectly by influencing other ecological factors.

Conclusions

Overall, the multiple factors in the micro-, meso-, exo-, macro-, and chronosystems can all influence bullying independently and also interdependently. Under certain ecological conditions, an individual may find harming weaker individuals may lead to more material, social, and reproductive advantages than under other ecological conditions. Accordingly, bullying behaviors are not limited to one specific demographic or environment. Instead, by exploring bullying from a holistic, evolutionary ecological framework, it is evident that bullying can be a facultative adaptation, providing numerous avenues for more effective anti-bullying efforts.

Fairness in Corvids

Zoe Johnson-Ulrich
Oakland University, Rochester, MI, USA

Synonyms

Birds; Crows; Equality; Justice

Definition

Understanding or being attentive to states of inequality, either in degree of effort towards a goal or in distribution of rewards or payoffs.

Introduction

A sense of fairness is a key component of morality and is a motivator of moral behavior (Allchin 2009). If other animals behave in a way to suggest they understand fairness, it suggests that they have some components of morality.

Evidence For Fairness

There is some evidence that two corvid species (crows and ravens) have a sense of fairness. This is displayed by the fact that they show “inequity aversion” – that is, when rewards are unequal, ravens and crows will refuse to take rewards or participate in tasks, despite the fact that this behavior minimizes their total rewards. Both ravens and crows will decrease participation in a task (such as exchanging a token for a food reward with a human experimenter) if they see another raven or crow receiving that reward for free or receiving a higher quality food item for the same task (Wascher and Bugnyar 2013). This shows sensitivity to equality of food rewards, but also of working effort; they expect a certain reward for a certain level of effort (Wascher and Bugnyar 2013).

On a cooperative problem-solving task where two strings had to be pulled simultaneously to bring food rewards into reach, ravens showed attentiveness to “cheaters” (Massen et al. 2015). When one raven monopolized both food rewards, the “cheated” raven was less likely to continue participation. This example, unlike the previous one, may be due to simple associative learning (i.e., when a raven does not get a reward for participation, it forms a negative association with cooperating, decreasing the likelihood of cooperating in the future; Massen et al. 2015). These appear to be the only examples of attention to fairness in any corvid species, but this is an area

of research that is still relatively new. Thus, more examples may emerge in the near future.

Conclusion

A sense of fairness is limited in corvids; the only evidence appears in two studies with ravens and crows. However, relatively little research has investigated fairness among corvids, and therefore more information of fairness and morality among different corvid species may be forthcoming.

Fairness in Nonhuman Primates

► [Fairness in Primates](#)

Fairness in Primates

Molly McGuire
Oakland University, Rochester, MI, USA

Synonyms

[Fairness in nonhuman primates](#); [Inequity aversion in primates](#)

Definition

Fairness is the preference for equality and resistance to an inequitable distribution of resources. This entry covers research on fairness in primates.

Introduction

It has been proposed that inequity aversion (or a sense of fairness) may have coevolved with cooperation (Brosnan and de Waal 2003). During cooperative efforts, it would be crucial from an adaptive standpoint, for individuals to be able to compare and measure their labors and rewards with the other members of their cooperative groups and react negatively to an unequal division of labor and rewards. As human beings are not the only species that display cooperation, it seems likely that those nonhuman animals that exhibit cooperation may also exhibit inequity aversion.

Evidence for Fairness

Brosnan and de Waal (2003) demonstrated that capuchin monkeys (*Cebus apella*), a cooperative species of primate, reacted negatively toward unequal distribution of food rewards. In their study, capuchin monkeys were trained in a task in which they exchanged a token with an experimenter for food. The monkeys were then placed in adjacent cages in which they could observe the interactions of a partner with the experimenter. There were two conditions: In the equality condition, both monkeys exchanged the token and were each rewarded with cucumber. In the inequality condition, one monkey was rewarded with cucumber (a less preferred food item), while the other was rewarded with grapes (a highly preferred food item) for completing the same task. They found that monkeys receiving cucumbers in the inequality condition were significantly less likely to complete the token exchange task. Incomplete exchanges were defined as the monkey failing to hand back the token for the offered reward item or failing to accept or consume the reward after handing back the token. In a follow-up experiment, Brosnan and de Waal (2003) then

introduced two additional conditions: the “effort control” condition in which one monkey continued to exchange the token for cucumber while their partner was given grapes without completing the task (no effort) and a “food control” condition in which there was no partner monkey (i.e., there was an empty cage into which grapes were placed). They found that the effects of the inequality condition were magnified in the “effort control” condition with the monkeys reacting even more negatively to the unequal distribution of rewards when their partner had put in no effort at all. They also found that the mere presence of grapes (in the “food control” condition) did not have an effect of rates of refusal (whether refusing to exchange the token or accept the reward). Brosnan and de Waal suggest that the rejection of a reward, which under most other circumstances is readily consumed, may indicate a violation of expectations – in this case an expectation of grapes.

Van Wolkenten et al. (2007) modified the methodology in the previous study in order to rule out the *greed hypothesis* (i.e., that the negative reaction of the monkeys was merely due to the visibility of the preferred food item) and the *frustration hypothesis* (i.e., that the negative reaction was due to the monkeys having received the preferred items in the immediate past). To rule out the *greed hypothesis*, preferred items were shown to the monkeys before each exchange. They found that displaying the grapes before each trial did not change the results (i.e., the monkeys still reacted negatively to inequality). To rule out the *frustration hypothesis*, they compared rates of refusal for trials which immediately followed trials rewarded with cucumber or trials rewarded with grapes, and they found no difference in responding. Further supporting the findings of Brosnan and de Waal (2003), Van Wolkenten et al. (2007) also found that the greater the effort of the subject, the more negative their response to the inequity of rewards.

Research has also investigated whether our closest relative, the chimpanzee (*Pan troglodytes*), has a sense of fairness using the same paradigm described above. Brosnan et al. (2010) found that chimpanzees also respond to inequity, but only in the context of performing a task. When a preferred reward was given to the partner

(without requiring a token exchange), the subject was less likely to respond negatively than when both had performed the exchange task. This may be due to the fact that the chimpanzees frequently receive food directly from keepers and so are not averse to some amount of inequality in the distribution of their daily diets. These researchers also found that the dominance hierarchy (rank) and sex also affected refusal rates in response to inequity, such that low-ranking or female chimpanzees were less likely to respond negatively to inequality than higher-ranking or male chimpanzees.

Conclusion

Similar to humans, it appears that both capuchin monkeys and chimpanzees judge fairness based off of the range of possible outcomes and how the rewards are then distributed. While the described research cannot explicitly determine the underlying motivations of the behaviors observed, the data do suggest that nonhuman primates may share some of the same underlying psychological mechanisms which would promote inequity aversion. One possible mechanism, social emotions (also known as “passions” by economists), is known to influence human responses to the distribution of resources and may play a role in non-human primates as well (Brosnan and de Waal 2003).

Fair-Weather Friends Versus True Friends

Adam Smith and Yohsuke Ohtsubo
Department of Psychology, Graduate School of
Humanities, Kobe University, Kobe, Japan

Synonyms

Fair-weather friends: Free-riders

Definition

Fair-weather friends are exploiters of true friendship who are interested in unilaterally receiving support. True friends (or close friends) not only receive support, they are also willing to provide support to each other in times of need.

Introduction

Friendship is a mutual support system between two non-kin individuals. Importantly, it is characterized by the provisioning of need-based support (Hruschka 2010; Silk 2003). Whereas a true friend is concerned about your welfare, happily helping you in times of need, a fair-weather friend is concerned only about his or her own welfare and thereby fails to help you when you need it most (Tooby and Cosmides 1996). Fair-weather friends are thus *free-riders* in the sense that they exploit the demands implicit within the friendship

contract. Many solutions have been proposed to this so-called free-rider problem, but the primary context in which they have been studied, namely, the iterated prisoner's dilemma (Axelrod 1984; Axelrod and Hamilton 1981), produces a solution (i.e., tit-for-tat reciprocity) which may not readily apply to the evolution of friendship. In this entry, we first summarize how fair-weather friends pose at least three different puzzles to the evolution of friendship and then introduce potential solutions to these puzzles.

Three Puzzles of Friendship

The evolution of friendship is associated with a set of difficult problems because need-based support appears vulnerable to exploitation by fair-weather friends. Friendship of this sort seems like an evolutionarily unstable strategy because need-based support not only requires people to ignore their partner's past behavior, it also necessitates that they disregard the prospect of future reciprocation – two important factors that enable reciprocal altruism to evolve. Moreover, even when a pair of friends mutually commit to a friendship, subtle suspicion might arise because it is not always clear that a current partner is indeed a true friend. As a result, such suspicion could lead to degradation or dissolution of the friendship.

Friends Turn a Blind Eye to Past Inequity

Friendship is generally considered as an instance of dyadic cooperation that is more or less unique to humans. Although the standard evolutionary model of dyadic cooperation is *reciprocal altruism* maintained by the *tit-for-tat* strategy (TFT) in the iterated prisoner's dilemma game (Axelrod 1984; Axelrod and Hamilton 1981; Trivers 1971), need-based support is incompatible with this strategy. Let us consider each of the qualities that characterize TFT: niceness, revengefulness, and forgivingness (Axelrod 1984). TFT is nice in the sense that it starts dyadic interactions by cooperating (an altruistic choice) and keeps cooperating as long as its partner behaves in kind. TFT is revengeful in the sense that it immediately

stops cooperating when its partner defects. Yet TFT is forgiving in the sense that it reverts to cooperating (i.e., ceases to defect) as soon as its partner reinitiates cooperation. Due to the last two characteristics (i.e., revengefulness and forgivingness), TFT can be conceived as an account-keeping strategy – it makes the balance between giving (its own cooperation) and receiving (its partner's cooperation) as even as possible.

Account-keeping (or tit-for-tat reciprocity) and need-based support appear to be two distinct forms of dyadic cooperation (e.g., Aktipis et al. 2011, 2016; Silk 2003). Before the existence of modern insurance systems, friendship was an essential source of support in the face of predicaments such as illness, injury, and failure to forage. Because these sorts of predicaments arise haphazardly, however, strict account-keeping is not amenable to these risks. If one individual (A), for example, suffers two or more successive instances of misfortune, while another individual (B) remains safe for a substantially long period of time, an imbalance between giving and receiving is a likely consequence: A would receive more from B than he/she would be able to provide in return. If B were to follow a strict account-keeping strategy, B would cut off assistance to A until he/she somehow reconciled the imbalance. This is a highly inefficient insurance system given the random nature of misfortune. In fact, agent-based simulations have revealed that need-based support, modeled after an extant form of friendship (*osotua*) among Maasai cow herders, is a more efficient risk-pooling strategy than strict account-keeping (Aktipis et al. 2011, 2016).

Furthermore, experimental evidence shows that friends are less concerned about the details of their partner's previous behavior than that of strangers or acquaintances (see Silk 2003, for a review). In other words, the real-world friendship appears to be much closer to a need-based system rather than an account-keeping system. However, due to a lack of contingencies for past behaviors (e.g., leniency regarding inequity), the need-based support system appears to be vulnerable to invasion from exploitative individuals, such as fair-weather friends. Therefore, the first puzzle of friendship is that true friendship appears to be

evolutionarily unstable in the presence of fair-weather friends.

Friends Cooperate Even When the Probability of Future Interaction Is Low

In their pioneering work on the evolution of friendship, Tooby and Cosmides (1996) proposed the notion of the *banker's paradox* to illuminate the puzzle of friendship. Because bankers must be selective in deciding in whom to invest their limited resources, “just when individuals need money most desperately, they are also the poorest credit risks and, therefore, the least likely to be selected to receive a loan” (Tooby and Cosmides 1996, p. 131). In a similar vein, although you would benefit most from having a true friend when you are in dire need (e.g., when you suffer serious illness, are on the verge of bankruptcy), “selection would seem to favour decision rules that caused others to desert you exactly when your need for help was greatest” (Tooby and Cosmides 1996, p. 132).

The banker's paradox is distinct from the account-keeping problem. Even when a partner has helped you before, you are better off withholding help from that partner when he or she might not survive the current predicament. In the repeated prisoner's dilemma game, if the number of interactions is a known quantity, any rational (i.e., benefit maximizing) player should defect on the very last round. However, when information about the last round is not available, it appears that a “shadow of the future” (or anticipated benefit from long-term cooperation) is the rationale for why players tend to cooperate in the iterated prisoner's dilemma. Indeed, formal evolutionary game analyses have revealed that the presence of sufficiently long-lasting interactions within the same dyad is the key ingredient for the evolution of dyadic cooperation (Nowak 2006). Therefore, if friendship is just a form of tit-for-tat reciprocity, it is expected that friends should be sensitive to the prospect of future interactions.

Nevertheless, people direct altruistic behavior toward their close friends even when reciprocation of a costly favor cannot be expected. For example, in an experimental game study, people

were more likely to help their close friends than non-close friends in an anonymous situation where no reciprocity was possible (Leider et al. 2009). Thus, the second puzzle is that friends appear to help each other even when the prospect of future interactions is conspicuously absent.

People have Difficulty Distinguishing True Friends from Fair-Weather Friends

Positive affect, manifested as feelings of warmth, intimacy, and closeness, is one of the universal characteristics of friendship (Hruschka 2010). In other words, friendship appears to be maintained by subjective mutual commitment (Nesse 2001). Notice that this observation basically paraphrases the idea that friendship is associated with the two abovementioned puzzles. If you subjectively commit to a relationship with a particular friend, you tend to help him/her regardless of his/her past behavior or prospects of his/her reciprocation. In addition, subjective commitment is associated with another, distinct puzzle. That is, it seems difficult to accurately assay your friend's commitment to you.

Suppose that one individual, A, subjectively commits to the relationship with B. However, this does not guarantee that B commits in a commensurate manner. When there is this sort of asymmetry in levels of commitment, the less committed partner can be considered a fair-weather friend. Imagine A helped B even though doing so was extremely costly. If there is no immediate subsequent opportunity for B to reciprocate, A might begin to doubt whether B really is a true friend. The presence of this suspicion of B's commitment would then lead to degradation of the committed relationship. To avoid this, both parties need to be able to accurately assay each other's commitment to the relationship. Nonetheless, the most accurate assessment is only possible in times of dire need. If your partner helps, he/she is a true friend; if not, he/she is a fair-weather friend. Therefore, the third puzzle is that friendship based on subjective commitment requires an accurate assessment of commitment levels, but this is not easily knowable until you, in fact, come to need your partner's help.

Possible Solutions to the Puzzles of Friendship

Researchers have proposed several solutions to the puzzles of friendship. Because the three puzzles are interrelated to each other, the proposed solutions are not necessarily mapped on to each of the three puzzles separately. The first solution, which applies to the first and second puzzles, is to make yourself *irreplaceable* to your friend (Tooby and Cosmides 1996). If you are irreplaceable, your friend would be compelled to commit to the relationship with you. In other words, irreplaceability ensures partner commitment. Accordingly, mutual irreplaceability can be a basis of true friendship. The second solution to the first two puzzles is to transform the incentive structure of staying in the current relationship. For example, introducing some *start-up cost* (Bergstrom et al. 2008) and increasing the benefits of staying in the current relationship (Roberts and Sherratt 1998) are two possible transformations of incentive structure. The solution to the third puzzle (i.e., how to accurately assess a partner's level of commitment) is to use honest signals of commitment (e.g., Yamagishi et al. 2005; Yamaguchi et al. 2015). If you can convince your partner of your true commitment to the relationship, degradation of the relationship due to suspicion can be avoided. Another solution to the third puzzle is to actively test your partner's commitment by imposing some stress on your partner; whether or not your partner can bare this stress tells you whether or not your partner is a true friend (e.g., Kelley 1983; Zahavi 1977).

Irreplaceability

Tooby and Cosmides (1996) proposed that making oneself irreplaceable to one's partner is a solution to the banker's paradox. Suppose that you can provide a service or material good that your partner cannot obtain from anyone else and that your partner depends on you alone for the good/service. Now imagine you suffer a serious injury, such as a snake bite, which puts your survival at risk. Although the prospect of future interactions is small, if your partner does not want to lose the good/service, he/she has no

option but to help you. This seemingly solves the banker's paradox because the partner's helping behavior is motivated by his/her own self-interest (i.e., maintaining the source of the otherwise unavailable good/service) rather than by the expectation of future reciprocation.

However, it is noteworthy that an irreplaceable individual, who can provide a useful good/service that no one else can provide, should be highly valued by everyone in the community. Suppose that a highly skilled hunter, who can hunt extremely large prey animals that no one else in the community can hunt, is valued by everyone in the community. If the hunter becomes sick, every member in the community will be incentivized to help him/her. This does not fit with a central archetype of friendship, that is, a dyadic mutual support system. Therefore, the sheer presence of some highly valued (i.e., irreplaceable) community members does not explain friendship.

Tooby and Cosmides further argue that some individual differences might cause the initial impetus of a runaway-like process of dyadic commitment formation. If you value a particular community member only slightly more than other members, you might be slightly more concerned about that member's welfare. Importantly, he/she might recognize that you are more willing to help him/her than others. This increases his/her concern about your welfare. Accordingly, he/she becomes more willing to help you when you are in dire need. This gives you another reason to value him/her. As this process continues, like the Fisherian runaway sexual selection process, mutual commitment becomes far stronger than expected from the initial subtle concern for each other's welfare. Once this process has sufficiently strengthened feelings of mutual irreplaceability, the banker's paradox is solved. You help a particular friend even when he/she is at risk of his/her life (and thus future reciprocation is less likely to be expected) because his/her survival influences your fitness.

This runaway friendship provides one solution to the banker's paradox. It assumes that even slight individual differences in interest in the welfare of particular others can initiate this dynamic process. However, it requires that each

individual is able to assess partner interest in his/her welfare. Remember that this is the third puzzle of friendship.

Start-up Costs and the Raise-the-Stakes

Friendship is generally assumed to develop gradually. Although in some cases people make a decision to form a friendship quickly at an early point in their acquaintance, the breadth and depth of interactions nevertheless progresses and increases over time (Hays 1988). If some significant period of time is necessary to develop a fully functioning, dependable friendship, deserting a current friend and attempting to make a new one can be costly. Deserters will at least temporarily lose access to the safety net that was provided by the previous friendship. Even if they easily find a new potential friend, it will take time to deepen their bonds. Thus, a "courtship" period serves as a start-up cost to friendship. Because of this start-up cost, the incentive to stay in a cooperative relationship with one's current partner increases (Bergstrom et al. 2008). Therefore, the incentive to behave as a fair-weather friend is substantially curtailed by start-up costs.

The apparent "courtship" period of friendship might serve another important purpose. A classic theory of relationship development, the social penetration theory (Altman and Taylor 1973), assumes that as social relationships develop, initial shallow social exchanges transition to deeper, more full-fledged social exchanges. This theory can be formalized using Roberts and Sherratt's (1998) *raise-the-stakes strategy*. In their evolutionary game analysis, players can choose not only their own behavior (i.e., cooperate or not) but also the level of cooperation, in the case that they have chosen cooperation. Suppose that each player is endowed with 10 units of a resource. Each player can choose how much of the 10 units he/she will transfer to his/her partner. The transferred resource will then be doubled and given to the partner. The raise-the-stakes strategy starts at a low level of cooperation (e.g., giving only 1 unit) and increases its level of cooperation if the partner's level of cooperation matches its own. By initiating the social exchange with a relatively trivial amount of a resource, each individual can avoid large exploitations by the partner at

early stages of relationship development. By the time both parties can exchange relatively large resources, the partner becomes irreplaceable (because replacing the current partner means that they incur the start-up cost inherent to a new relationship). Experimental studies have revealed that people in fact gradually increase the stakes of social exchanges over the course of relationship development (Roberts and Renwick 2003; Yamagishi et al. 2005).

Applying the raise-the-stakes logic to the context of random predicaments, Hruschka (2010) revealed that the following rule of thumb can be adaptive: “Always help [your friend], unless there is some reason to believe he is not a friend” (p. 239). This rule of thumb is adaptive when erroneously deserting true friendship is more costly than erroneously committing to a fair-weather friend. In particular, if you have helped your partner on successive occasions but your friend has not reciprocated due to lack of opportunities, this rule of thumb tells you to stay in the relationship because you do not yet have convincing evidence that the partner is a fair-weather friend. In other words, Hruschka analytically showed that relative indifference to precise equity is adaptive in the context of mutual support provisioning.

Commitment Signals

Runaway friendship formation and the raise-the-stakes strategy explain how the capacity for subjective commitment can be adaptive. As both parties progressively commit to a particular friendship, the incentive to desert the current friend decreases. Recall that for this runaway-like process to progress, each individual must be able to recognize his/her partner’s subtle commitment to the relationship. Nevertheless, a partner’s level of subjective commitment is not necessarily transparent, and uncertainty about partner commitment undermines dynamic increases in mutual commitment. Moreover, the conditional part of Hruschka’s (2010) rule of thumb (i.e., “unless there is some reason to believe he is not a friend”) also requires some cue to distinguish fair-weather friends from true friends.

Yamagishi et al. (2005) devised a game setting where each player cannot only raise the stakes but also signal one’s commitment to the relationship. In their model, each player chooses a level of dependence on the partner. If A chooses a high-stakes game rather than a low-stakes game, A benefits more from B’s cooperation, but also loses more from B’s exploitation. Therefore, A can move to the high-stakes game when and only when he/she trusts B. Because A’s choice of the high-stakes game is potentially costly (i.e., A becomes more vulnerable to B’s exploitation), A’s choice serves as an honest signal of A’s trust in B. If B knows that A trusts him/her, B immediately recognizes that A is his/her valuable exchange partner. This may provide a reason for B to (at least slightly) prefer A as an interaction partner because B knows that A values him/her but does not know whether others value him/her as much as A does. Therefore, A’s signal of trust can serve as an initial impetus to start runaway-like friendship formation between A and B.

Making oneself vulnerable (i.e., performing a costly behavior to demonstrate sincere trust) is not the only way to communicate commitment to a relationship (Yamaguchi et al. 2015). Friends occasionally make some small sacrifices for their partner (e.g., missing a favorite TV show to go out with friends). Friends regularly exchange small, and thus less costly, gifts (Hruschka 2010). Friends pay attention to how each other are doing (Ohtsubo et al. 2014). These commitment signals might not appear sufficiently costly to convince the signal recipient that the signaler is indeed a true friend. However, people can only send such signals to a limited number of partners. Time and social attention are both finite resources, and the resource allocation problem forces signal senders to limit the number of recipients (Ohtsubo et al. 2014; Sutcliffe et al. 2012). Accordingly, these relatively less costly signals may be sufficient to dispel suspicions that the signaler is not a friend. This is the information that Hruschka’s (2010) rule of thumb requires, and it is possibly sufficient to start the runaway-like friendship formation process that leads friends to be mutually irreplaceable.

Testing the Strength of a Bond

If both partners do not spontaneously send any commitment signals, can either party know the partner's level of commitment? In fact, friends might actively test their partner's commitment by imposing some stresses on each other (Kelley 1983; Zahavi 1977). This is called a *bond testing*. Although your friend may fail to make a spontaneous sacrifice for you, he/she may be willing to do so if you explicitly ask. Basically, bond testing involves soliciting some costly commitment signal from partners. If your partner tolerates the stressful situation you impose upon them, this means that your friend is committed to the relationship with you.

Although bond testing has not yet been well-studied in humans, some primatologists use this notion to explain otherwise unexplainable primate behaviors. For example, Perry (2011) observed that pairs of white-faced capuchin monkeys (*Cebus capucinus*) mutually insert their partner's finger into their own eye sockets. This is an extremely dangerous behavior in that it might lead to damage to the eye or even a loss of vision. Therefore, one might not engage in such a dangerous behavior with someone whom he/she cannot fully trust. In other words, the joint engagement in such a dangerous behavior reveals strong mutual commitment. Accordingly, Perry interprets this dangerous behavior as a bond-testing ritual. Human instances of bond testing in the context of friendship seem to merit further research.

Conclusion

Friendship is characterized by need-based support provisioning. Unlike account-keeping reciprocity, friendship is especially vulnerable to the presence of free-riders (i.e., fair-weather friends). We pointed out three interrelated puzzles that pertain to the evolution of friendship. First, without strict account-keeping (i.e., behaving in a manner contingent with a partner's previous behavior), friendship is vulnerable to invasion by fair-weather friends. Second, without concern for the shadow of the future, one might misplace one's investment in a partner who is unlikely to

reciprocate (i.e., the banker's paradox). Third, even when friends have a capacity for subjective commitment, without a way of confirming this commitment, mutually committed relationships may be susceptible to doubt and deteriorating trust. We presented two possible solutions to the former two problems: making oneself irreplaceable to one's partner and using the raise-the-stakes strategy. These two solutions can make friendship adaptive to the extent that individuals have some ability to keep track of a partner's current level of commitment to the relationship (but perfect precision is not needed). This problem may be solvable by commitment signals. For example, if someone commits to a particular relationship, that person may regularly give small gifts or simply pay attention to his/her partner's needs. Although these behaviors are relatively low cost compared to the tangible support required in the times of real need, they may still serve as sufficient signals of friendship. Alternatively, friends may occasionally engage in active tests of their partner's commitment. These behavioral tendencies (to signal one's commitment or test a partner's commitment) are necessary to maintain the "nearly" unconditional altruism that is characteristic of friendship.

Synonyms

Counterfactual mental states; False perceptions; Mentalizing; Mindreading; Pretense; Psychological reasoning; Reality-incongruent beliefs; Representational mental states; Theory of mind

Definition

False-belief understanding requires understanding (at least implicitly) that the mind is representational in nature and, as such, can hold beliefs that are inaccurate or that deviate from reality in some way.

Introduction

Adults make sense of others' actions by inferring the mental states that underlie these actions; this ability is variously referred to as psychological reasoning, mind reading, mentalizing, or exhibiting a theory of mind. Over the past two decades, numerous reports have presented evidence that psychological reasoning emerges early in life: When infants observe an agent act in a simple scene, they infer the agent's motivational (e.g., goal, attitude) and epistemic (e.g., knowledge, ignorance) states, and they use these mental states to predict and interpret the agent's subsequent actions and to guide their own responses to the agent (for a review, see Baillargeon et al. 2016). Such early competencies naturally give rise to the following questions: How similar is infants' psychological reasoning to that of older children and adults? Is there substantial continuity across development, or do fundamental changes take place in the types of mental states that can be attributed to agents?

When Does False-Belief Understanding Emerge?

For many years, it was generally assumed that a major shift does take place around 4 or 5 years of age in the development of psychological reasoning: Children become capable of understanding false beliefs and other counterfactual mental states (Wellman et al. 2001; Wimmer and Perner 1983). This conclusion was based mainly on evidence from *elicited-prediction* tasks in which children must answer a test question about the likely behavior of an agent who holds a false belief about a scene. In the classic Sally-Anne task

(Baron-Cohen et al. 1985), for example, children listen to a story enacted with props: Sally hides a marble in one of two containers and then leaves; in her absence, Anne moves the marble to the other container; Sally then returns, and children are asked the test question, "Where will Sally look for her marble?" Beginning at age 4 or 5, children answer correctly and point to the marble's original location; in contrast, younger children point to the marble's current location, as though they are unable to understand that Sally holds a false belief about the marble's location. This developmental pattern – from below-chance to above-chance performance – was consistently observed in different elicited-prediction tasks and in different cultures around the world (Wellman et al. 2001). Based on these results, many researchers came to regard false-belief understanding as a hallmark of advanced or full-fledged psychological reasoning. In essence, success at elicited-prediction tasks was taken to demonstrate that children finally grasp the representational nature of the mind: They realize that beliefs are mental representations and, as such, can deviate from reality.

In recent years, however, the conclusion that false-belief understanding is not attained until the preschool years has been called into question, as evidence has steadily accumulated that toddlers (age 2–3) and infants (under age 2) succeed at simpler false-belief tasks (for reviews, see Baillargeon et al. 2016; Carruthers 2013). To date, converging demonstrations of early false-belief understanding have been obtained in *spontaneous-response* and *elicited-intervention* tasks; key findings with each type of task are summarized in the next sections.

Spontaneous-Response Tasks

In a spontaneous-response false-belief task, children watch a scene in which an agent comes to hold a false belief, and their spontaneous responses to the unfolding scene are measured. The first spontaneous-response task administered to infants (Onishi and Baillargeon 2005) used the *violation-of-expectation* method, which takes advantage of infants' natural tendency to look

False Beliefs, Fig. 1 In the task of Onishi and Baillargeon (2005), 15-month-olds first received familiarization trials in which an agent hid a toy in a green box (trial 1) and then reached into the box as though to grasp her toy (trials 2 and 3). In the belief-induction trial, infants saw one of four events: While the agent watched, the yellow box moved toward the green box and then returned to its starting position (true-belief-green condition); in the agent's absence, the toy moved from the green to the

yellow box (false-belief-green condition); the toy moved to the yellow box in the agent's presence (true-belief-yellow condition); the toy again moved to the yellow box in the agent's presence but then returned to the green box after she left (false-belief-yellow condition). In the test trials, the agent reached into either the yellow box (yellow-box trial) or the green box (green-box trial) and then paused

longer at events that violate, as opposed to confirm, their expectations (Fig. 1). In the task, 15-month-olds first received familiarization trials

in which an agent hid a toy in a green as opposed to a yellow box. Next, infants received one of four different belief-induction trials that resulted in the

agent believing, truly or falsely, that the toy was in the green or the yellow box: In the true-belief-green condition, the agent watched as the yellow box moved a short distance and then returned to its original position; in the false-belief-green condition, the agent was absent when the toy moved from the green box into the yellow box; in the true-belief-yellow condition, the agent saw the toy move into the yellow box; finally, in the false-belief-yellow condition, the agent watched as the toy moved into the yellow box, but was absent when it returned to the green box. In the test trial, the agent reached into either the green or the yellow box and then paused. In each condition, infants expected the agent to act on the information available to her, whether it was true or false. Thus, infants in the true-belief-green and false-belief-green conditions expected the agent to reach into the green box, whereas infants in the true-belief-yellow and false-belief-yellow conditions expected her to reach into the yellow box; in each case, infants detected a violation (as indexed by longer looking times) when the agent searched the other box.

These results suggested that infants can already attribute false beliefs to agents. Subsequent investigations extended these results in many different directions.

Different Spontaneous Responses

Evidence of early false-belief understanding has been obtained not only in violation-of-expectation tasks such as that of Onishi and Baillargeon (2005) but also in other types of spontaneous-response tasks. In *anticipatory-looking* tasks, 17- to 25-month-olds visually anticipated that an agent who falsely believed an object was in location-A (when it was in fact in location-B or had been removed from the scene) would search location-A for the object (Southgate et al. 2007; Surian and Geraci 2012). In *anticipatory-pointing* tasks, 18-month-olds spontaneously pointed to inform an agent who falsely believed an object was in location-A that the object had been moved to a new location (Knudsen and Liszkowski 2012). In *preferential-looking* tasks, 2.5-year-old toddlers who were told a false-belief story accompanied by pictures looked preferentially at the final picture that correctly, as opposed to

incorrectly, completed the story (Scott et al. 2012). In *affective-response* tasks, 2.5-year-olds expressed more tension in their facial expressions when an agent who was approaching a container was mistaken, as opposed to ignorant, about some aspect of its contents (Moll et al. 2017).

Researchers have also obtained evidence of early false-belief understanding in spontaneous-response tasks tapping neural (as opposed to behavioral) responses. In a *neural-prediction* task, 6-month-olds showed an increase in sensorimotor alpha-band suppression (an EEG correlate of action prediction) when an agent falsely believed a box contained a ball, but they showed no such increase when she falsely believed the box was empty. Infants thus anticipated that the agent would search for the ball when she falsely believed it was present, but not when she falsely believed it was absent (Southgate and Vernetti 2014). Finally, in a *neural-occlusion* task, 8-month-olds showed an increase in temporal gamma-band activation (an EEG correlate of sustained object representation during occlusion) when an agent falsely believed an object was behind an occluder (unbeknownst to the agent, the object disintegrated once occluded); infants showed no such increase when the agent witnessed the object's disintegration (Kampis et al. 2015).

Different False Beliefs

Infants and toddlers in spontaneous-response tasks have been found to represent false beliefs about the *location* (Onishi and Baillargeon 2005), *presence* (Southgate and Vernetti 2014), *identity* (Scott and Baillargeon 2009), and *nonobvious properties* (Scott et al. 2010) of objects. In a task on identity (Scott and Baillargeon 2009), for example, 18-month-olds first received familiarization trials in which an agent faced a one-piece penguin that did not come apart and a disassembled two-piece penguin (Fig. 2). In each trial, the agent hid a small key in the bottom piece of the two-piece penguin and then assembled it; once assembled, the two-piece penguin was identical to the one-piece penguin. In the test trials, while the agent was absent, an experimenter assembled the two-piece penguin, placed it under a transparent cover, and then placed the

False Beliefs, Fig. 2 In the task of Scott and Baillargeon (2009), 18-month-olds first received familiarization trials involving two toy penguins that were identical except that one could come apart (two-piece penguin) and one could not (one-piece penguin). In each trial, as an agent watched, an experimenter's gloved hand placed the disassembled two-piece penguin and the one-piece penguin on platforms (trials 1 and 2) or in shallow boxes (trials 3 and 4); next, the agent hid a small key in the bottom piece of the two-piece penguin and then assembled it. During the test trials, while the agent was absent, the gloved hand assembled the two-piece penguin, covered it with a transparent cover, and then covered the one-piece penguin with an opaque cover. The agent then returned, reached for either the transparent cover (transparent-cover trial) or the opaque cover (opaque-cover trial), and then paused

Familiarization trials

Test trials

one-piece penguin under an opaque cover. The agent then returned with her key, reached for either the transparent or the opaque cover, and then paused. Infants expected the agent to reach for the opaque cover and looked longer when she reached for the transparent cover instead (this looking pattern reversed if the agent witnessed the experimenter's actions). These results indicated that infants attributed to the agent two

interlocking false beliefs: They expected her (a) to mistake the penguin visible under the transparent cover for the one-piece penguin (because the two-piece penguin had always been disassembled at the start of the familiarization trials) and hence (b) to falsely conclude that the disassembled two-piece penguin was hidden under the opaque cover (because both penguins were always present in the familiarization trials).

Additional findings confirmed that infants could distinguish between false belief and ignorance: When both covers were opaque, infants held no particular expectation about which cover the agent would reach for.

Implanting False Beliefs

Infants and toddlers in spontaneous-response tasks have been shown to reason correctly not only about the actions of agents who *hold* false beliefs (e.g., where they will search for a hidden object or which object they will select to produce a desired effect) but also about the actions of deceptive agents who seek to *implant* false beliefs in others. In a task with 17-month-olds (Scott et al. 2015), a thief attempted to secretly steal a desirable rattling toy during its owner's absence by substituting a less desirable silent toy (Fig. 3). Infants first watched a series of rattling-toy and silent-toy familiarization trials. In each rattling-toy trial, the owner entered with a toy on a tray; she shook the toy, which rattled, placed it back on the tray, and then left. In her absence, the thief picked up the toy, shook it, and then replaced it on the tray. When the owner returned, she stored the rattling toy in a treasure box. The silent-toy trials were similar except that the toy was silent, the thief did not play with it, and the owner discarded it in a trash can when she returned. In the test trial, the owner brought in a rattling test toy that was visually identical to a silent toy she had previously discarded in the trash can. As before, she shook the toy and then left. In her absence, the thief picked up the rattling toy, peered into the trash can, and selected either the matching silent toy (matching trial) or a nonmatching silent toy (nonmatching trial). The thief placed the silent toy on the owner's tray, hid the rattling test toy in a pocket, and then paused. Infants looked significantly longer if they received the nonmatching as opposed to the matching trial, suggesting that they realized that (a) the thief sought to steal the rattling test toy without the owner's knowledge by substituting a discarded silent toy the owner could mistake for the rattling test toy, and (b) the thief could achieve this deceptive goal only by substituting the matching silent toy. In a control experiment, the owner always shook her toy again

when she returned in the familiarization trials, before storing or discarding it. Infants now looked equally during the matching and nonmatching trials, suggesting that they realized that the owner could not be deceived by the substitution of either the nonmatching silent toy (she would detect the substitution as soon as she saw the toy) or the matching silent toy (she would detect the substitution as soon as she shook the toy).

Different Linguistic Demands

Toddlers have been shown to succeed at spontaneous-response tasks with no linguistic demands (Southgate et al. 2007) as well as spontaneous-response tasks with high linguistic demands comparable to those of elicited-prediction tasks (Barrett et al. 2013; Scott et al. 2012). In a preferential-looking task (Scott et al. 2012), for example, 2.5-year-olds listened to a false-belief story, accompanied by a picture book, about a character named Emily and her apple. In the final double page of the book, one picture showed Emily searching for her apple where she falsely believed it to be (original-location picture), and the other picture showed Emily searching for her apple in its current location (current-location picture). Upon hearing the final line of the story, which stated that Emily was looking for her apple, children looked preferentially at the original-location picture, suggesting that they represented Emily's false belief and understood how it would guide her actions. Similar results were obtained in three traditional non-Western societies: a Salar community in China, a Shuar community in Ecuador, and a Yasawan community in Fiji (Barrett et al. 2013). These results make clear that the reason why young children fail at elicited-prediction tasks but succeed at spontaneous-response tasks cannot be that the former are highly verbal whereas the latter are not: Young children can succeed at highly verbal spontaneous-response tasks.

Elicited-Intervention Tasks

In an elicited-intervention task, children watch a scene in which an agent comes to hold a false
